To summarize the above, it can be stated that it has not so far been demonstrated with certainty that the monomer in the amount released during such procedures as total hip replacement has any general pharmacological side effects on human patients. Cardiovascular complications during hip replacement are more readily explained on the basis of systemic fat embolism. A possible hypothesis is that of a combined effect or even an interaction between monomer and fat embolism in the sense that the monomer is partly responsible for the development of fat emboli. And the high polymerization temperature of the cement may also be of significance in this respect.

The only study referring to a combined effect has been one by Schlag et al (1973) who studied various cardiovascular functions in rabbits and dogs during intrafemoral

application of acrylic cement. They advanced the hypothesis that circulatory decompensation results from an increased pulmonary vascular resistance to which three factors contribute. Fat and bone marrow emboli are held responsible for mechanical obstruction of the pulmonary microcirculation believed to be further aggravated by the release (potentiated by the bone marrow emboli) of a thromboplastin like substance giving rise to platelet aggregates. The last suggestion was also made by Modig et al (1973a). The third factor directly attributed to the monomer is described to produce oedema of the alveolocapillary membrane in the lungs which via reduction of the pulmonary microcirculation will contribute to increased pulmonary vascular resistance which could end in acute cor pulmonale.

The possibility of interaction between monomer and fat embolism on the other hand was suggested in studies by Dustmann et al (1972) and Koch et al (1972). They demonstrated histological features of extensive pulmonary embolism in six out of eight cats submitted to subtrochanteric femoral osteotomy reaming of the medullary cavity and intramedullary implantation of bone cement. When the cement application was preceded by pressure relieving suction drainage mild fat embolism was demonstrable in only five out of ten animals. Fat embolism was likewise only slight when a different substance (Plasteline) was introduced into the medullary cavity without suction drainage. This fat embolism became more marked when liquid monomer was introduced into the femoral shaft in addition. When the procedure was repeated this time applying acrylic cement after intravenous injection of 5 ml of the fat emulsifier choline phospholipid (Lipostabil) only two of the ten animals showed slight pulmonary fat embolism. Of the ten animals in which the Lipostabil injection was combined with suction drainage of the medullary cavity none developed pulmonary fat embolism. The authors concluded from these results that the monomer is of essential significance in the causation of fat embolism.

In conclusion, it can be stated that even though no definite results have been reached, it can safely be admitted that application of acrylic cement, particularly in the femoral shaft, is known to cause a slight decrease in blood pressure and occasionally severe hypotension. It seems therefore advisable to observe a number of rules. The surgeon should ensure optimal mixing as long as possible outside the organism and provide adequate ventilation of the femoral shaft. The endoprosthesis should moreover be eased into its proper position. Points of importance to the anaesthetist are to ensure adequate filling of the circulating volume before introduction of acrylic cement, and prevention of even slight hypoxia. The possible contribution of the cytotoxic monomer to local tissue necrosis remains unknown.

## 12.7 Allergy

So far there have been no indications of significant allergic complications caused by acrylic cement (and particularly by the monomer methyl methacrylate) in orthopaedic applications. Sensitization to the monomer as reported in dermatological and dental literature (Slooff 1970, Charnley 1970), however, has been described in orthopaedic surgeons with contact

dermatitis (Pegum and Medhurst 1971 Blair Fries et al 1974) and in patients after total hip replacement with the aid of bone cement (Blair Fries et al 1974) The monomer seems to penetrate surgical gloves readily

Until the contrary is proved the possibility that allergic reactions with serious consequences for the patient can be provoked by the cement components or additives must be taken into account (Bloch and Hastings 1972 Muller 1974b)

## 1 2 8 Carcinogenic effect

Partly in view of reports on sarcomatous degeneration after application of PMMA in test animals (Contzen et al 1967 Slooff 1970 Charnley 1970) the Food and Drugs Administration has long delayed acceptance of acrylic cement in the USA Finally in 1971 only one product (Simplex P) was accepted There has been one case report on malignant degeneration following surgical application of PMMA

Some 18 years after application of Lucite for extrapleural plombage of a tuberculous pulmonary process an extraskeletal chondrosarcoma was found in the supraclavicular fossa which proved to be directly related to the fibrous capsule enveloping the Lucite (Thompson and Enin 1969)

So far as could be established no malignant degeneration has ever been ascribed to any orthopaedic application of PMMA. However after exposure of the human organism to recognized carcinogens it may be 20 35 years before a malignancy becomes manifest (Ott 1970 Lavorgna et al 1972) In view of the long latent period no definite conclusion can as yet be reached about the carcinogenic effect of acrylic cement on the human organism Discriminate use and prolonged follow ups particularly on younger patients are therefore imperative

## 1 3 *Histopathological reactions*

### 1 3 1 Introduction

In descriptions given in the past of the effect of PMMA on living tissue distinction must be made between tissue changes occurring in reaction to

- polymerized PMMA
- b PMMA setting in situ

All authors quoted by Contzen et al (1967) Slooff (1970) and Charnley (1970) regard polymerized acrylic cement as a biocompatible material The principal reaction mentioned is the development of a connective tissue membrane at the interface between PMMA and living tissue

When this material is exposed to stress, signs of chronic inflammation are seen in the connective tissue layer, with reactive necrosis and increased remodelling in adjacent bone tissue. These reactions can increase due to disintegration of the PMMA and, together with mechanical imperfections, this ultimately led to rejection of the Judet type of Plexiglas prosthesis as mechanically and biologically unsuitable.

The situation of PMMA setting in situ – the acrylic bone cement – is a different one. It is in fact highly dubious whether this could be described as a biocompatible substance. The possible untoward local side effects of the bone cement, most important among which are the high polymerization temperature and the cytotoxicity of the non polymerizing monomer, become manifest in contact with the living organism. The histopathological reactions which acrylic cement provokes in living human tissue can be divided into reactions in soft tissues and those in bone.

### 1.3.2 Reactions in the soft tissues

After total hip arthroplasty, the movable parts of the artificial joints come to be surrounded by a new connective tissue capsule which replaces the capsule which is (usually) excised during the operation. The histopathology of this new capsule, removed in revision operations or post mortems, has been described by Cotta and Schultz (1970), Semlitsch et al (1971), Willert (1973a), Willert and Semlitsch (1973b, 1974a), Beneke et al (1973), Charosky et al (1973), Masshoff and Neuhäus-Vogel (1974), Evans et al (1974) and Brinkmann and Hülmann (1974).

Although the structure of the new capsule shows some resemblance to that of a normal joint capsule, yet an identical tissue structure is never attained. The tissue structure shows changes and is much coarser because regenerative processes in the new connective tissue are accompanied by a tissue reaction to the presence of foreign bodies. These foreign bodies are wear products of metal and plastic prosthesis components and bone cement particles from the implant bed.

According to Willert and Semlitsch (1973b, 1974a) acrylic cement particles are a major factor in the development of and the reactions in the new capsule. They are held to contribute more to these than the wear products of the prosthesis components. In the new capsule these foreign bodies produce a typical partly granulomatous foreign body reaction which varies with the degree of wear and other factors such as infection, instability of the prosthesis and excessive amounts of acrylic cement. The chronic foreign body reaction maintained by constant addition of newly formed wear particles leads to progressive thickening and cicatrization of the new capsule and over a long period of time this can produce

some loss of mobility in the artificial joint (Willert and Semlitsch 1973b 1974a)

The granulation tissue tends to become necrotic and necrotic material can be recovered in the form of cheese like debris from large pouches which have formed in the new capsule. The wear particles are eliminated in minute amounts via the perivascular lymph interstices (Willert 1973a Willert and Semlitsch 1973b 1974a Brinkmann and Heilmann 1974). If this elimination is insufficient or if the supply is too large then this may lead in the long run to resorption of bone required for fixation of the cement with consequent loosening of the prosthesis components (Willert and Semlitsch 1974a).

Evans et al (1974) maintain that hypersensitivity to metal wear particles can lead to several reactions which via obliteration of supplying blood vessels give rise to necrosis of the bony implant bed and ultimately cause loosening of the prosthesis.

The development of this capsule should be carefully watched because it may give rise to pain functional impairment loosening of the prosthesis and even possible sarcomatous degeneration (Willert and Semlitsch 1973b 1974a Charosky et al 1973). Although careful studies by the authors mentioned on page 26 have fortunately failed to demonstrate malignant degeneration following the use of acrylic cement in allo-arthroplasties Willert and Semlitsch (1973b) and Charosky et al (1973) nevertheless stress the potential risks entailed by chronic progressive cicatrization on the basis of a foreign body reaction in this context.

### 1.3.3 Reactions in bone

Charnley (1970) described the histopathological changes of bone in contact with acrylic cement with reference to postmortem findings obtained in 23 patients who had shown an uneventful clinical course after implantation of an artificial joint which had remained stably fixed in the bone for many years (longest period reported 7 years). He observed that a thin layer of bone tissue (0.5 mm thick) in direct contact with the acrylic cement had become necrotic. At the interface between bone and acrylic cement a connective tissue membrane had formed which contained giant cells but showed none of the typical signs of chronic inflammation. From this connective tissue membrane a fibrocartilaginous tissue had developed by metaplasia induced by mechanical pressure. In this tissue there were sometimes ossified areas in contact with underlying bone tissue. Dead bone had in part been replaced by new osteons which at some sites lay against the cement. However Charnley (1970) considered above all the fibrocartilaginous layer to be essential for the transmission of forces from cemented prosthesis to bony implant bed.

On the basis of these observations and biomechanical theories (Charnley 1965) and supported by his good long term clinical and radiological results, Charnley (1970) described acrylic cement as a safe material which – although not yet ideal – meets all mechanical and biological requirements

Willert and Puls (1972) studied the histological reaction of bone to acrylic cement (Palacos) in 23 cases of total hip arthroplasty or hemi arthroplasty of the hip. The material was obtained at postmortem the operations having been performed 7 days to 5 years before this examination

In all patients whose operation dated back more than 10 weeks, the implant had borne weight and the clinical result had been satisfactory. In all cases fixation of cement to bone was macroscopically firm, and no mobility between cement and bone tissue was demonstrable. Intimate interlocking of the cement in the interdigitations of the cancellous trabeculae was found in the metaphysis. Along the compact bone of the diaphysis and along the acetabular floor the cement did exactly follow the bone surface, but at these sites the bone architecture happens to be less suitable for fixation as firm as that is possible in cancellous bone. In these areas the cement consequently showed a much smoother surface. Necrosis was found in a thin layer of bone (up to 3 mm) surrounding the cement and large necrotic foci were found in the cancellous bone of the greater trochanter and in the medullary cavity of the femoral diaphysis distal to the point of the stem of the prosthesis. Willert and Puls (1972) distinguished three phases in the tissue reactions to the implanted bone cement

- a the initial phase, lasting up to 2-3 weeks after implantation
- b the phase of reparation extending from 3 weeks to a year or longer,
- c the phase of stabilization, which was completed after a maximum of two years

These three phases were best described in terms of microscopic features

*In the initial phase* fat cells and haemopoietic cells in the bone marrow degenerated. There was lipophagia by polynuclear phagocytes which closely resembled foreign body cells. The cancellous bone showed necrosis of cancellous trabeculae at sites of contact with the cement. The extent of necrosis in the diaphyseal compact bone showed marked interindividual changes ranging from an area of 0.5-0.8 mm to one third of the inner surface of the cortex<sup>1</sup>

*The phase of reparation* was characterized by organization of the bone marrow, necrosis to fibrosis in which avital bone marrow elements were still demonstrable after as long as one year. The boundary with the vital bone marrow was demarcated by a hyperaemic marginal zone. Beginning in areas where the bone marrow had been revitalized remodelling processes were taking place in the necrotic bone. Osteogenesis took place by metaplasia of connective tissue in which woven bone was deposited

or by deposition of new bone lamellae on old necrotic cancellous trabeculae. In the diaphyseal compact bone mostly lamellated bone was deposited on the interior wall of the haversian canals. Bone trabeculae anchored in the cement could disappear entirely due to osteoclastic bone destruction with formation of lacunae especially in cortical bone. The bone remodelling was not confined to the primarily necrotic areas. It was observed also in cancellous or compact bone areas not directly adjacent to the implant, with predominance of bone destruction. This produced rarefaction in the cancellous bone and porosity of compact bone. The features of characteristic osteoclastic osteoporosis could be further enhanced by pre-existent bone atrophy as seen in elderly patients. The phase of reparation was found to be completed about 7 years after the operation. All necrotic tissue had been replaced by vital bone marrow and bone and the bone cement was found surrounded everywhere by a thin layer of vital bone tissue.

In the phase of stabilization a collagenous connective tissue membrane of 0.1-1.5 mm thickness was found as remnant of the above described bone marrow fibrosis. This membrane contained lymphocytes, plasma cells and polynuclear foreign body giant cells. The bone marrow otherwise had a normal structure. In the bone this phase was characterized by further remodelling with as conspicuous feature reorientation in the course of the bone trabeculae. While initially these had been arranged perpendicular to the bone cement, they were chiefly found to run more or less parallel to the cement surface in the phase of stabilization. Total bony enclosure of the acrylic was not observed anywhere in the material examined. By far the largest part of the interface consisted of bone marrow which showed a smooth or latticed meshwork structure. This bone marrow was separated from the cement by a connective tissue membrane in which in the phase of stabilization also haemorrhagic areas with fibrin deposits were seen.

In the initial phase the anchoring of cement in bone was most secure even though the interlocking bone trabeculae were usually avital. Due to remodelling and reorientation of the bone trabeculae interlocking of these trabeculae in the cement was much less in evidence in the phase of stabilization. For the most part, the bone was not in direct contact with cement but separated from it by a thin zone of flat polynuclear cells. These cells were probably to be regarded as the equivalent of the giant cells in the cement/bone marrow interface. Wherever there was more space between bone and cement in the phase of stabilization smooth or latticed meshwork marrow was found separated from the cement by a connective tissue membrane.

The intensity of the changes described varied from case to case and therefore the interval required for revitalization of necrosis and the healing process also varied. The impression was gained moreover that after early mobilization and weight bearing the processes of degeneration and regeneration of bone were better balanced and led to less extensive osteoporosis.

The above described findings roughly correspond with those of Charnley but they have been differently interpreted by Willert and Puls (1972) and Willert et al (1974b). They maintained that the implant of prosthesis with cement owes its stability to anchoring in bone. In their view connective tissue membrane regenerated bone marrow and soft tissues grown into the cement may mechanically function as a buffer which absorbs excessive forces impinging on the implant. They believe that the haemorrhages and exudates found in the connective tissue membrane corroborate this. In their opinion the bone cannot be expected to interlock as intimately with

the cement during revitalization of the necrotic foci as at the time of insertion of the prosthesis. According to Willert and Puls (1972), therefore, the anchoring in bone is never afterwards so firm as at the time when the cement is setting immediately after implantation<sup>1</sup>

Despite ■ favourable initial clinical course following a technically perfect operation, minimal movements between bone and implant can eventually occur due to diminution of the firmness of bony anchoring, as described by Charnley (1970), Willert and Puls (1972) and Willert et al (1974b). Should the demands made upon the implant exceed the strength of the cement/bone anchoring (and this is often unpredictable), instability of the implant inevitably results. A series of microfractures in the interface upon continued stress can lead to loosening and even fracture of the cement (Homsy 1973, Willert et al 1974b). The tissue changes in the implant bed might very well lead to late loosening of the prosthesis. It ■ therefore of importance to make an attempt at answering the ever-repeated question about the possible cause of this necrosis. The three possibilities suggested are interference with the bone vascularization at operation, the high maximum polymerization temperature of the cement, and the cytotoxicity of the monomer.

#### 1.4 Summary

- 1 Acrylic bone cement as applied in joint replacing operations has generally fulfilled expectations
- 2 Polymerization entails the development of a high temperature and the release of non polymerizing cytotoxic monomer. At a local level these side effects might contribute to necrosis involving a thin layer of the bony implant bed. We do not know whether this necrosis is caused by the untoward side effects of cement setting in the living organism or whether a vascular factor is (also) responsible
- 3 The general pharmacological toxicity of the monomer methylmethacrylate, in the amounts commonly used in acrylic cement, is not alarming
- 4 Sensitization and carcinogenic effects of acrylic cement used for orthopaedic purposes have so far been unknown, but cannot be excluded with certainty in the long run
- 5 Several factors exert a negative influence on the mechanical qualities of PMMA. Shrinkage of acrylic cement could well be an unfavourable factor of some importance
- 6 Cement particles can contribute to an unmistakable extent to the reactive development of a greatly thickened new joint capsule

## CHAPTER 2

# THE VASCULARIZATION OF DIAPHYSEAL CORTICAL BONE AND THE REACTIONS TO DISTURBED MEDULLARY CIRCULATION

### 2.1 Introduction

The direct relationship between vascularization and osteogenesis has been recognized for centuries but it is only in the past 25 years that attention and studies have focused on the anatomy of the osseous circulation on a microscopic level (Trueta 1968 Brookes 1971)

On the one hand this can be explained by the development of more advanced equipment to process bone and by the fact that perfected perfusion techniques have made it possible also to visualize microscopically small vessels. On the other hand the more aggressive attitude adopted in the past few decades by orthopaedic surgery in dealing with congenital and acquired anomalies of the musculo-skeletal system may also have given impetus to the renewed interest.

Our knowledge of the cortical circulation of diaphyseal bone in mammals which for decades was based on the works of Langer (1876) Lexer et al (1904) and Johnson (1927) has been expanded in the years after World War II mainly by the results of animal experiments. It has been established that man and (test) animal regardless of species show the same basic patterns (Tilling 1958 Rhineland 1962 1972 Kookenberg 1963 Trueta 1968 Brookes 1971).

The arterial vascularization of a long bone has three sources: the nutrient artery, the metaphyseal arteries (in combination with the epiphyseal vessels after closure of the growth plate) and the periosteal arterioles.

### 2.2 The vascularization of diaphyseal cortical bone

#### 2.2.1 Topographic anatomy of the vascularization of the diaphysis of the rabbit femur

The *nutrient artery* of the rabbit femur arises from the lateral circumflex femoral artery. Over a distance of 2 cm it extends distally along the

lateral aspect of the iliopsoas tendon (Shim et al 1970) and enters the nutrient foramen. This foramen extends obliquely to the knee and is localized on the medioposterior side of the femoral shaft, immediately distal to the lesser trochanter (Brookes & Harrison 1957). In the foramen the nutrient artery produces no branches. Once in the medullary cavity after passing through the foramen it divides into ascending and descending vessels whose branches supply the bone marrow and the cortex with blood (figure 2). In the cortex arterioles which can be followed at best to a point halfway the cortex ultimately open up into the Haversian canals and Volkmann's canals which contain one or two endothelium lined vessels the size of a capillary (Brookes 1971; Rhinelander 1974).

Among the *metaphyseal* arteries the artery of the trochanteric fossa which arises from the medial circumflex femoral artery merits some attention because according to Brookes & Harrison (1957) and Brookes (1971) it could be a second afferent vessel for the diaphysis. This artery enters through a foramen in the depth of the trochanteric fossa (Barone et al 1973) and divides into ascending branches which supply the greater and lesser trochanter as well as the femoral neck with blood. The third trochanter (gluteal tuberosity of the femur) has no separate nutrient artery. In addition branches of the trochanteric anastomosis and the arterial ring at the base of the femoral neck enter the metaphysis through many foramina. The distal femoral metaphysis is supplied by numerous metaphyseal arteries whose fairly thick branches penetrate the cortex through many foramina (Rogers & Gladstone 1950; Brookes & Harrison 1957; Brookes 1964).

The growing *epiphysis* has its own separate vascularization and until completion of growth the growth plate constitutes a vascular barrier between the epiphyseal and the metaphyseal system (Trueta & Morgan 1960; Kockenbergh 1963; Trueta & Cavadias 1964).

It is probably only at the capillary level that the medullary arteries anastomose with the metaphyseal vessels; after closure of the growth plate anastomoses with the epiphyseal arteries probably do exist but have not been demonstrated with any certainty (Brookes 1971). According to Brookes (1964, 1971) this would imply that generally speaking under physiological conditions the diaphyseal, metaphyseal and epiphyseal systems supply only their own region with blood. According to Shim et al (1970) the nutrient artery accounts for at least 70 per cent of the circulation of diaphysis and bone marrow in which the other systems

Transverse section (C) through a normal rabbit femur at the level of the passage of the nutrient artery through the cortex. Also note the accompanying vein and arterioles and two nerves (HE x 63).

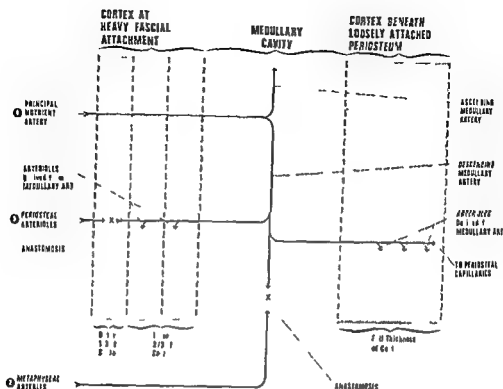

Fig. 3 Rhinelander's diagram showing the afferent vascular system of a mature long bone and its distribution

Components 1, 2 and 3 constitute the total arterial blood supply to the diaphyseal cortex. Arrows indicate direction of blood flow.

Adopted from Rhinelander F. W. *Circulation in Bone*. In: *The biochemistry and physiology of bone* (G. H. Bourne, ed.) 2nd edition, vol. II, pp. 177. Academic Press, New York, 1972 (with the publisher's consent).

contribute about 30 per cent. Under normal conditions each of the regional systems accounts for at least two thirds of the circulation of its primary supply region (Shim 1968). Trueta (1959, 1968) also refutes the notion that these systems consist of end arteries.

On the capillary level there is a direct communication between the *periosteal* network supplied by the periosteal arterioles and the cortical capillaries. At sites of muscle attachment (*linea aspera*) where the fibrous periosteum is firmly anchored to the bone, the intramuscular and the periosteal circulation merge. The vascularization at these sites is more abundant than elsewhere in the periosteum (Brookes 1971; Rhinelander 1972, 1973).

A large number of *venous sinusoids* supplied by intracortical capillaries and medullary veins drain into a central intramedullary canal which

extends throughout the length of the diaphysis and drains into the two venous metaphyseal systems. This central venous sinus is many times as wide as the nutrient artery but has a much thinner wall. According to de Marnette (1951) and Tilling (1958), there are no valves in it. In the diaphysis the nutrient vein is the sole ramification (Brookes & Harrison 1957, Morgan 1959, Brookes 1971).

## 2.2.2 Functional anatomy

A more profound insight into the significance of the above described systems can be gained when we consider the contribution of each system to the cortical vascularization of a long bone in the functional sense. Two relevant theories merit a more detailed discussion.

### 2.2.2.1 Singular circulation concept

According to Brookes (1971) and Rhinelander (1972) the medullary circulation made up by the nutrient artery and also partly by the metaphyseal arteries through anastomoses on a capillary level is responsible solely for the afferent cortical circulation. They therefore maintain that, under physiological conditions, the direction of flow in the diaphyseal cortex is centrifugal.

The periosteal network plays a subordinate role in the afferent circulation. Possibly it contributes to the vascularization of a few superficial lamellae and this is probably the case in immature cortical bone lined with a richly vascularized periosteum (Rhinelander 1974). Rhinelander (1971, 1973) attaches special significance to the periosteal arterioles in the vicinity of muscle attachments (*linea aspera*) which in this limited sector are believed to vascularize one-quarter to one-third of the outer layers of compact bone. The afferent vascular system is schematically represented in figure 3.

Certainly in mature cortical bone the periosteal vessels are to be regarded as the final link in the efferent system. The punctate haemorrhages which occur when periosteum is stripped off vital bone indicate that blood leaves the cortex here. Venous blood from the intermediate system made up by Volkmann's canals and Haversian canals which constitutes the link between the afferent and the efferent system ultimately drains through cortical venous canals into the extraosseous (periosteal) vascular network (Rhinelander 1972, 1974). The periosteal capillaries, which communicate with the cortical capillaries of the superficial cortical lamellae, should also be regarded as a component part of the efferent system. It is mainly the medullary sinusoids and the central

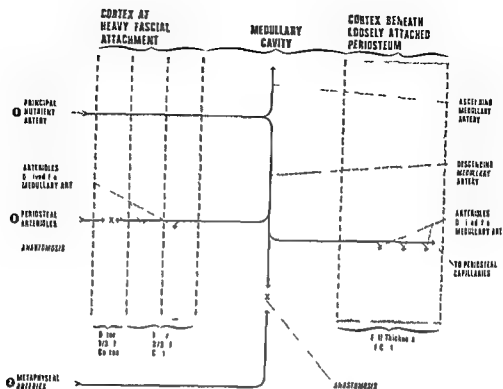

Fig. 3 Rhinelander's diagram showing the afferent vascular system of a mature long bone and its distribution

Components 1, 2 and 3 constitute the total arterial blood supply to the diaphyseal cortex. Arrows indicate direction of blood flow.

Adopted from Rhinelander F. W. *Circulation in Bone*. In *The biochemistry and physiology of bone* (G. H. Bourne ed.) 2nd edition vol. II pp. 177. Academic Press, New York, 1972 (with the publisher's consent).

contribute about 30 per cent. Under normal conditions each of the regional systems accounts for at least two thirds of the circulation of its primary supply region (Shim 1968). Trueta (1959, 1968) also refutes the notion that these systems consist of end arteries.

On the capillary level there is a direct communication between the *periosteal network* supplied by the *periosteal arterioles* and the *cortical capillaries*. At sites of muscle attachment (*linea aspera*), where the fibrous periosteum is firmly anchored to the bone, the *intramuscular* and the *periosteal* circulation merge. The vascularization at these sites is more abundant than elsewhere in the periosteum (Brookes 1971, Rhinelander 1972, 1973).

A large number of *venous sinusoids* supplied by *intracortical capillaries* and *medullary veins* drain into a central *intramedullary canal* which

extraosseous arterioles penetrated the periosteal callus and vascularized osteoclastic removal of necrotic bone of the anterior and both lateral cortices. This extraosseous circulation however, was transient and was reduced to normal proportions as soon as the normal medullary system had sufficiently regenerated. When physiological conditions are interfered with therefore — e.g. by interventions which completely block the medullary blood flow — the direction of flow through cortex may be reversed by supply from the extraosseous system. This new extraosseous circulation originates from soft tissues surrounding the fractured long bone and is a transient phenomenon (Rhinelander 1972). Gothman (1960a, 1960b) as well has shown that the extraosseous supply comes from the soft tissues. It disappears after regeneration of the medullary circulation.

## 2.2.2.2 Dual circulation concept

The concept outlined above has been refuted by Trueta & Cavadias (1955, 1964), Trueta (1963, 1968) and Crock (1967) — one of Trueta's co-workers. They agree that the medullary system to which the nutrient artery contributes some 70 per cent while the metaphyseal and epiphyseal arteries account for the remaining 30 per cent is the most important system for the vascularization of the diaphyseal cortex. But they restrict this to the inner two thirds of the compact bone maintaining that here the centrifugal flow encounters a centripetal flow originating from the periosteal vessels which in their opinion supply the outer one third of the cortex. They hold that the efferent venous flow from the cortex is mainly through the medullary venous system. This view was supported by the experiments of Langer (1876), Johnson (1927), Foster et al. (1951), Gothman (1960a), Larson et al. (1961) and Hockenberg (1963).

They advanced their hypothesis on the basis of experiments with young and mature rabbit radii in which the contribution made by each of the three sources of vascularization was determined by blocking the other two (Trueta & Cavadias 1964). For example after blocking the metaphyseal vessels and severing the nutrient artery in young and mature animals they found that the outer one half to one third of the cortex remained vital. Johnson's findings (1927) were identical. After severance of the nutrient artery and suppression of the periosteal blood flow by stripping off the periosteum and placing a thin polythene sheath around the bone one half to two-thirds of the inner cortex retained its vitality as long as the medullary circulation was taken over by anastomoses with the metaphyseal system. If this did not happen (young animals) then total necrosis of the cortex resulted. Similar results were reported after ligation of the nutrient artery and stripping of the periosteum in dog tibiae by Johnson (1927) in rabbits femurs by Foster et al. (1951) and

venous sinus that are responsible for the drainage of bone marrow products. These enter the medullary venous system by virtue of the permeability of the sinus endothelium, or by phagocytosis (Brookes 1971).

The above outlined concept of a centrifugal one way afferent circulation of cortical diaphyseal bone, originally advanced by Brookes & Harrison (1957) has been corroborated by MacNab (1957, 1958), MacAuley (1958), Jackson & MacNab (1959), and Nelson et al (1960). And it has been elaborated and substantiated in excellent micro angiographic studies by Rhinelander and his co-workers. Suffice it here to present a summary of their principal results.

Using fine granulated barium sulphate (Micropaque) as perfusion medium, the micro angiograms were studied microscopically and stereoscopically, and correlated to the histology of sections originating from the same tissue slices. Throughout the healing process of non dislocated radial and ulnar fractures in mature dogs the medullary circulation, which had remained intact, continued to dominate. External callus was supplied by extraosseous circulation (Rhinelander et al 1962). In the case of dislocated fractures, however, with interruption of the medullary circulation, an increased periosteal or extraosseous circulation was found initially to be the primary source of vascularization for the forming callus (Rhinelander et al 1968a). A typical feature was the course of these vessels perpendicular to the cortex. Three to six weeks after fracture infliction, the medullary circulation had regenerated and resumed its prominent place in the blood supply to the callus and the devitalized fracture fragments. This process proved to be as much accelerated as reduction of the fracture had been more exact. In radial osteotomies followed by stable plate fixation reconstruction of medullary vessels was observed after only one week (Rhinelander 1968b, 1972). The significance of the temporarily increased extraosseous vascularization gradually diminished and ultimately even the periosteal callus was supplied from the medullary circulation. In the final stage of remodelling the normal pattern of vascularization returned, in which medullary vessels anastomosed with the periosteal vessels where they entered in the outer layers of the cortex at fascial attachments (Rhinelander 1968a, 1968b). Even after destruction of the medullary circulation by osteotomy of the tibia (Rhinelander 1965) or the ulna (Rhinelander et al 1967) in dogs followed by insertion of a loose fitting intramedullary rod the medullary circulation proved to have enormous regenerative powers. Insertion of a tight fitting nail after reaming of the medullary cavity through a femoral osteotomy resulted in temporary devascularization of the entire cortex with the exception of a small posterior sector near the linea aspera (Rhinelander 1973). The medullary circulation regenerated gradually and finally supplied the entire cortex with blood. In the intermediate phase (8 weeks) of healing

extraosseous arterioles penetrated the periosteal callus and vascularized osteoclastic removal of necrotic bone of the anterior and both lateral cortices. This extraosseous circulation however was transient and was reduced to normal proportions as soon as the normal medullary system had sufficiently regenerated. When physiological conditions are interfered with therefore, e.g. by interventions which completely block the medullary blood flow the direction of flow through cortex may be reversed by supply from the extraosseous system. This new extraosseous circulation originates from soft tissues surrounding the fractured long bone and is a transient phenomenon (Rhinelander 1972). Gothman (1960a, 1960b) as well has shown that the extraosseous supply comes from the soft tissues. It disappears after regeneration of the medullary circulation.

## 2.2.2.2 Dual circulation concept

The concept outlined above has been refuted by Trueta & Cavadias (1955, 1964), Trueta (1963, 1968) and Crock (1967), one of Trueta's co-workers. They agree that the medullary system to which the nutrient artery contributes some 70 per cent while the metaphyseal and epiphyseal arteries account for the remaining 30 per cent is the most important system for the vascularization of the diaphyseal cortex. But they restrict this to the inner two-thirds of the compact bone maintaining that here the centrifugal flow encounters a centripetal flow originating from the periosteal vessels which in their opinion supply the outer one third of the cortex. They hold that the efferent venous flow from the cortex is mainly through the medullary venous system. This view was supported by the experiments of Langer (1876), Johnson (1927), Foster et al. (1951), Gothman (1960a), Larson et al. (1961) and Kookenberg (1963).

They advanced their hypothesis on the basis of experiments with young and mature rabbit radii in which the contribution made by each of the three sources of vascularization was determined by blocking the other two (Trueta & Cavadias 1964). For example, after blocking the metaphyseal vessels and severing the nutrient artery in young and mature animals they found that the outer one half to one third of the cortex remained vital. Johnson's findings (1927) were identical. After severance of the nutrient artery and suppression of the periosteal blood flow by stripping off the periosteum and placing a thin polythene sheath around the bone, one half to two-thirds of the inner cortex retained its vitality as long as the medullary circulation was taken over by anastomoses with the metaphyseal system. If this did not happen (young animals) then total necrosis of the cortex resulted. Similar results were reported after ligation of the nutrient artery and stripping of the periosteum in dog tibiae by Johnson (1927), in rabbits femurs by Foster et al. (1951) and

in dog femurs by Larson et al (1961) The differences observed between young and mature animals would have to be explained on the basis of the insufficiency of the metaphyseal medullary anastomoses in the young animals and the presence of the vascular barrier which the growth plate erects between epiphyseal and metaphyseal vessels (Trueta & Cavadias 1964)

Finally, if only the nutrient artery was left intact, most of the cortex was found to retain its vitality, and only the outer one quarter showed necrosis This observation, too, confirmed Johnson's experiment (1927) Trueta found evidence substantiating the existence of a dual circulation in his observation (1963 1968, p 167) that two or even three vessels extended in opposite direction in a single Haversian canal This finding, however, has never been corroborated by other investigators (Brookes 1971) except Brånemark (1959) The most prominent critics of the dual circulation concept have been Brookes and Rhinelander

### 2 2 2 3 Refutation of the dual circulation concept

According to Brookes (1971) the observation of cortical necrosis following stripping of the periosteum and its replacement with a plastic sheath is understandable as a consequence of venous obstruction Rhinelander (1972) also criticized this way of suppressing physiological functions The remarkable fact is that the opponents make use of the same weapon i.e. both Brookes (1971, p 122) and Trueta (1968 p 168) find support for their arguments in a study by Nelson et al (1960) Referring to a vascular study of human tibiae these authors stated 'we agree with several recent studies (Brookes 1958 Brookes & Harrison 1957 MacNab 1957) that indicate that the periosteal vessels are of little significance in supplying arterial blood to the normal tibia

More recent studies also seem to decide the issue in favour of Brookes and Rhinelander The dominant importance of the medullary circulation was likewise convincingly demonstrated by Danckwardt Lilliestrom (1969), Danckwardt Lilliestrom et al (1970a) and Olerud & Danckwardt Lilliestrom (1971) Indian ink micro angiography and fluorochrome labelling were among the methods used in all the animal experiments next to be described

In the first study (Danckwardt Lilliestrom 1969) the medullary circulation of growing and mature rabbits was destroyed by reaming brushing or suction After these procedures the periosteal blood vessels initially proved capable of taking over nearly the entire cortical circulation As early as one week after the operation newly formed blood vessels had penetrated the medullary cavity Four weeks after the operation the reaction in the periosteal vessels had diminished and the medullary

circulation had sufficiently regenerated to revascularize the inside of the cortex. After eight weeks there was no longer any difference in luminal width and depth of vascularization of the periosteal vessels between the test side and the control side. In other words, the pattern of vascularization had returned to normal. In all animals the medullary cavity contained newly formed vessels which, in all growing rabbits and some 50 per cent of the mature animals, were identifiable as thick walled arteries and in all animals as normal sinusoids. After reaming and brushing of the medullary cavity in mature dog femurs the totally destroyed vascularization was found to have started regeneration within one week. Three weeks after the operation the revascularization of the medullary cavity was nearly complete and one week later it was complete. The reactive periosteal vascularization was found to have returned to normal after six weeks.

In another experiment (Danckwardt Lilliestrom et al 1970a) the medullary cavity of mature rabbit tibiae was reamed according to Hunscher whereupon a dome shaped transverse osteotomy was fixed under compression with a specially designed medullary nail. To promote rigid fixation of the osteotomy surfaces, the mid portion of the nail consisted of a massive metal cylinder with a length of 3.5 cm and a diameter which was 100 micra smaller than that of the burr last used. However since the medullary cavity is not circular in cross section but triangular (proximal segment) or rectangular (distal segment) it was not quite occluded by the nail used. This procedure resulted in total destruction of the intramedullary circulation. At the level of the osteotomy the periosteal vessels too showed discontinuity over a distance of 1 cm on either side of the cut surface.

The material was divided into two groups. In the first group bone marrow was drained by suction through a separate aperture during reaming whereupon an osteotomy was performed and the nail inserted. In the second group there was no suction of bone marrow during reaming. Marked differences in general reactions, severity of cortical necrosis, revascularization and fracture healing were observed between the two groups. An explanation of these differences will be offered on page 45.

The vascular reaction did not differ in principle from that in the first experiment. The first group (suction) showed quick restoration of the endosteal circulation, blood vessels were observed in the medullary cavity after one week and the medullary circulation had largely regenerated after four weeks. This process took a considerably slower course in the second (non suction) group.

In a third experiment (Olerud & Danckwardt Lilliestrom 1971) dog tibiae were submitted to a double osteotomy with a Gigli saw removing an annular diaphyseal segment whereupon the cut surfaces were filed smooth. Next the avascular fragment was reinserted and fixed in situ by means of a plate mounted under compression. A study of the healing

in dog femurs by Larson et al (1961) The differences observed between young and mature animals would have to be explained on the basis of the insufficiency of the metaphyseal-medullary anastomoses in the young animals and the presence of the vascular barrier which the growth plate erects between epiphyseal and metaphyseal vessels (Trueta & Cavadias 1964)

Finally, if only the nutrient artery was left intact, most of the cortex was found to retain its vitality, and only the outer one quarter showed necrosis This observation, too, confirmed Johnson's experiment (1927) Trueta found evidence substantiating the existence of a dual circulation in his observation (1963, 1968, p 167) that two or even three vessels extended in opposite direction in a single Haversian canal This finding, however, has never been corroborated by other investigators (Brookes 1971) except Brånemark (1959) The most prominent critics of the dual circulation concept have been Brookes and Rhinelander

### 2 2 2 3 Refutation of the dual circulation concept

According to Brookes (1971) the observation of cortical necrosis following stripping of the periosteum and its replacement with a plastic sheath is understandable as a consequence of venous obstruction Rhinelander (1972) also criticized this way of suppressing physiological functions The remarkable fact is that the opponents make use of the same weapon, i.e. both Brookes (1971, p 122) and Trueta (1968 p 168) find support for their arguments in a study by Nelson et al (1960) Referring to a vascular study of human tibiae, these authors stated 'we agree with several recent studies (Brookes 1958, Brookes & Harrison 1957 MacNab 1957) that indicate that the periosteal vessels are of little significance in supplying arterial blood to the normal tibia'

More recent studies also seem to decide the issue in favour of Brookes and Rhinelander The dominant importance of the medullary circulation was likewise convincingly demonstrated by Danckwardt Lilliestrom (1969) Danckwardt Lilliestrom et al (1970a) and Olerud & Danckwardt Lilliestrom (1971) Indian ink micro angiography and fluorochrome labelling were among the methods used in all the animal experiments next to be described

In the first study (Danckwardt Lilliestrom 1969) the medullary circulation of growing and mature rabbits was destroyed by reaming, brushing or suction After these procedures the periosteal blood vessels initially proved capable of taking over nearly the entire cortical circulation As early as one week after the operation newly formed blood vessels had penetrated the medullary cavity Four weeks after the operation the reaction in the periosteal vessels had diminished and the medullary

sometimes a few avital remnants of bone marrow. This blood clot is organized by in growth of markedly dilated vessels and new bone marrow cells can be found from the end of the first postoperative week on (e.g. Danckwardt Lilliestrom 1969). Initially there is predominantly degradation of necrotic material with as striking features the presence of macrophages (Foster et al 1951, Trueta & Cavadias 1955, Richany et al 1965) and later of polynuclear giant cells (Bragdon et al 1949, de Marneffe 1951, Trueta & Cavadias 1955, 1964, Brookes 1960). Trueta & Cavadias (1964) found these giant cells in young and mature rabbits as long as eight and six months respectively after blocking the medullary circulation (cf. page 37).

Dependent on the operative lesion a fibrous network forms in the medullary cavity (Brookes 1960, Richany et al 1965); this contains osteogenetic granulation tissue from which woven trabecular bone can be formed (Foster et al 1951, Bränemark et al 1964, Richany et al 1965, Danckwardt Lilliestrom 1969, Lindwer 1972). As bone marrow regeneration continues this new bone is resorbed (Danckwardt Lilliestrom 1969).

Foster et al (1951) and Richany et al (1965) reported that in their experiments bone trabeculae were still found centrally in the medullary cavity six months after operation. None of the investigators has described cartilage formation. Only Richany et al (1965) and Mital and Cohen (1966) have ventured to explain the appearance of new bone in the medullary cavity following intramedullary operations. They suggested that pluripotent reticulum cells proliferate and then differentiate to mature bone marrow elements. These include osteoblasts which form trabecular bone during reorganization of the bone marrow. This bone formation in the medullary cavity was not observed in experiments in which after extramedullary or intramedullary interruption of the medullary circulation the medullary cavity was filled with foreign matter in the form of an intramedullary nail (Kuntzsch 1940, 1962, Trueta & Cavadias 1955, Gothman 1960b, Koelenberg 1963, Gustilo et al 1964, Anderson 1965, Rhinelander 1967, 1973, Danckwardt Lilliestrom et al 1970a), wax (Mc Nab 1958), plaster of Paris (Slooff 1972) or acrylic cement (Wiltse et al 1947, Slooff 1970, 1971, 1972, Lindwer 1972, 1975).

### 2.3.2 Cortical reactions

Within 24 hours of an intramedullary lesion or extraosseous blocking of the medullary circulation incipient necrosis of the endosteal cortex can be observed in the form of shrinkage and hyperchromasia of cell nuclei (Foster et al 1951, Trueta & Cavadias 1964, Richany et al 1965). After a week the endosteal lining has become frayed or has

process revealed that four-fifths of the revascularization of this fragment was accounted for by the destroyed medullary vessels, which had regenerated after four weeks (shortest observation period) The presence of the plate on the medial aspect of the tibia exerted no influence on this process, because the pattern of revascularization on the lateral aspect of the tibia was identical

## 2 2 3 Conclusion

The evidence supplied by the above mentioned authors through their highly original experiments lends further substance to the assumption that the concept advanced by Brookes (1971), with the modification introduced by Rhinelanders (1972) for the vascularization of diaphyseal bone is the more plausible of the two concepts discussed Under normal conditions the periosteal system is of subordinate importance for the cortical blood supply Under changed conditions however, the extraosseous vessels prove to be of transitory importance After shaft fractures the medullary circulation remains dominant After complete interruption of the medullary circulation the centrifugal direction of flow may be reversed temporarily and the extraosseous system of healing bone may become the principal source of revascularization of the cortex

## 2 3 Description of the reactions to disturbed medullary circulation

The circulation in the medullary arterial system, which has been described above as the principal source of the vascularization of the diaphyseal cortex can be partly or totally destroyed in various ways The ischaemia caused by intramedullary procedures has a number of typical consequences for the bone The reactions provoked in medullary cavity cortex and periosteum are so characteristic and reproducible as to justify a joint discussion of all relevant animal experiments carried out in the past The intensity of these reactions largely depends on the extent of the lesion, the animal species involved and the degree of maturity of the animals For a comprehensive review of the literature on intramedullary procedures we may refer to Danckwardt Lilliestrom (1969 pp 17 22) and Danckwardt Lilliestrom et al (1970a pp 3 12)

### 2 3 1 Medullary reactions

Medullary devascularization leads to necrosis of the bone marrow After an intramedullary procedure one initially finds a blood clot with,

sometimes, a few avital remnants of bone marrow. This blood clot is organized by in growth of markedly dilated vessels and new bone marrow cells can be found from the end of the first postoperative week on (e.g. Danckwardt Liljestrom 1969). Initially there is predominantly degradation of necrotic material with as striking features the presence of macrophages (Foster et al 1951, Trueta & Cavadas 1955, Richany et al 1965) and later of polynuclear giant cells (Bragdon et al 1949, de Marneffe 1951, Trueta & Cavadas 1955, 1964, Brookes 1960). Trueta & Cavadas (1964) found these giant cells in young and mature rabbits as long as eight and six months respectively after blocking the medullary circulation (cf. page 37).

Dependent on the operative lesion a fibrous network forms in the medullary cavity (Brookes 1960, Richany et al 1965) this contains osteogenetic granulation tissue from which woven trabecular bone can be formed (Foster et al 1951, Brånemark et al 1964, Richany III et al 1965, Danckwardt Liljestrom 1969, Lindwer 1972). As bone marrow regeneration continues this new bone is resorbed (Danckwardt Liljestrom 1969).

Foster et al (1951) and Richany et al (1965) reported that in their experiments bone trabeculae were still found centrally in the medullary cavity six months after operation. None of the investigators has described cartilage formation. Only Richany et al (1965) and Mital and Cohen (1966) have ventured to explain the appearance of new bone in the medullary cavity following intramedullary operations. They suggested that pluripotent reticulum cells proliferate and then differentiate to mature bone marrow elements. These include osteoblasts which form trabecular bone during reorganization of the bone marrow. This bone formation in the medullary cavity was not observed in experiments in which after extramedullary or intramedullary interruption of the medullary circulation the medullary cavity was filled with foreign matter in the form of an intramedullary nail (Kuntzsch 1940, 1962, Trueta & Cavadas 1955, Githman 1960b, Joekenberg 1963, Gustilo et al 1964, Anderson 1965, Rhinelander 1967, 1973, Danckwardt Liljestrom et al 1970a), wax (Mc Nab 1958), plaster of Paris (Slooff 1972) or acrylic cement (Wiltse et al 1957, Slooff 1970, 1971, 1972, Lindwer 1972, 1975).

### 2.3.2 Cortical reactions

Within 24 hours of an intramedullary lesion or extraosseous blocking of the medullary circulation incipient necrosis of the endosteal cortex can be observed in the form of shrinkage and hyperchromasia of cell nuclei (Foster et al 1951, Trueta & Cavadas 1964, Richany et al 1965). After a week the endosteal lining has become frayed or has

process revealed that four fifths of the revascularization of this fragment was accounted for by the destroyed medullary vessels, which had regenerated after four weeks (shortest observation period). The presence of the plate on the medial aspect of the tibia exerted no influence on this process, because the pattern of revascularization on the lateral aspect of the tibia was identical.

### 2 2 3 Conclusion

The evidence supplied by the above mentioned authors through their highly original experiments lends further substance to the assumption that the concept advanced by Brookes (1971), with the modification introduced by Rhinelanders (1972) for the vascularization of diaphyseal bone is the more plausible of the two concepts discussed. Under normal conditions the periosteal system is of subordinate importance for the cortical blood supply. Under changed conditions, however, the extraosseous vessels prove to be of transitory importance. After shaft fractures the medullary circulation remains dominant. After complete interruption of the medullary circulation the centrifugal direction of flow may be reversed temporarily and the extraosseous system of healing bone may become the principal source of revascularization of the cortex.

### 2 3 *Description of the reactions to disturbed medullary circulation*

The circulation in the medullary arterial system which has been described above as the principal source of the vascularization of the diaphyseal cortex can be partly or totally destroyed in various ways. The ischaemia caused by intramedullary procedures has a number of typical consequences for the bone. The reactions provoked in medullary cavity, cortex and periosteum are so characteristic and reproducible as to justify a joint discussion of all relevant animal experiments carried out in the past. The intensity of these reactions largely depends on the extent of the lesion, the animal species involved and the degree of maturity of the animals. For a comprehensive review of the literature on intramedullary procedures we may refer to Danckwardt-Lilliestrom (1969 pp 17-22) and Danckwardt-Lilliestrom et al (1970a pp 3-12).

#### 2 3 1 Medullary reactions

Medullary devascularization leads to necrosis of the bone marrow. After an intramedullary procedure one initially finds a blood clot with

sometimes a few avital remnants of bone marrow. This blood clot is organized by in growth of markedly dilated vessels and new bone marrow cells can be found from the end of the first postoperative week on (e.g. Danckwardt Lilliestrom 1969). Initially there is predominantly degradation of necrotic material with as striking features the presence of macrophages (Foster et al 1951 Trueta & Cavadias 1955 Richany et al 1965) and later of polynuclear giant cells (Bragdon et al 1949 de Marnette 1951 Trueta & Cavadias 1955 1964 Brookes 1960) Trueta & Cavadias (1964) found these giant cells in young and mature rabbits as long as eight and six months respectively after blocking the medullary circulation (cf page 37).

Dependent on the operative lesion a fibrous network forms in the medullary cavity (Brookes 1960 Richany et al 1965) this contains osteogenetic granulation tissue from which woven trabecular bone can be formed (Foster et al 1951 Brånemark et al 1964 Richany et al 1965 Danckwardt Lilliestrom 1969 Lindwer 1972). As bone marrow regeneration continues this new bone is resorbed (Danckwardt Lilliestrom 1969).

Foster et al (1951) and Richany et al (1965) reported that in their experiments bone trabeculae were still found centrally in the medullary cavity six months after operation. None of the investigators has described cartilage formation. Only Richany et al (1965) and Mital and Cohen (1966) have ventured to explain the appearance of new bone in the medullary cavity following intramedullary operations. They suggested that pluripotent reticulum cells proliferate and then differentiate to mature bone marrow elements. These include osteoblasts which form trabecular bone during reorganization of the bone marrow. This bone formation in the medullary cavity was not observed in experiments in which after extramedullary or intramedullary interruption of the medullary circulation the medullary cavity was filled with foreign matter in the form of an intramedullary nail (Kuntscher 1940 1962 Trueta & Cavadias 1955 Gothman 1960b Kockenberg 1963 Gustilo et al 1964 Anderson 1965 Rhinelander 1967 1973 Danckwardt Lilliestrom et al 1970a) wax (Mc Nab 1958) plaster of Paris (Slooff 1972) or acrylic cement (Wiltse et al 1957 Slooff 1970 1971 1972 Lindwer 1972 1975).

### 2.3.2 Cortical reactions

Within 24 hours of an intramedullary lesion or extraosseous blocking of the medullary circulation incipient necrosis of the endosteal cortex can be observed in the form of shrinkage and hyperchromasia of cell nuclei (Foster et al 1951 Trueta & Cavadias 1964 Richany et al 1965). After a week the endosteal lining has become frayed or has

process revealed that four-fifths of the revascularization of this fragment was accounted for by the destroyed medullary vessels, which had regenerated after four weeks (shortest observation period). The presence of the plate on the medial aspect of the tibia exerted no influence on this process, because the pattern of revascularization on the lateral aspect of the tibia was identical.

## 2 2 3 Conclusion

The evidence supplied by the above mentioned authors through their highly original experiments lends further substance to the assumption that the concept advanced by Brookes (1971), with the modification introduced by Rhinelanders (1972) for the vascularization of diaphyseal bone is the more plausible of the two concepts discussed. Under normal conditions the periosteal system is of subordinate importance for the cortical blood supply. Under changed conditions, however, the extraosseous vessels prove to be of transitory importance. After shaft fractures the medullary circulation remains dominant. After complete interruption of the medullary circulation the centrifugal direction of flow may be reversed temporarily and the extraosseous system of healing bone may become the principal source of revascularization of the cortex.

## 2 3 Description of the reactions to disturbed medullary circulation

The circulation in the medullary arterial system, which has been described above as the principal source of the vascularization of the diaphyseal cortex, can be partly or totally destroyed in various ways. The ischaemia caused by intramedullary procedures has a number of typical consequences for the bone. The reactions provoked in medullary cavity, cortex and periosteum are so characteristic and reproducible as to justify a joint discussion of all relevant animal experiments carried out in the past. The intensity of these reactions largely depends on the extent of the lesion, the animal species involved and the degree of maturity of the animals. For a comprehensive review of the literature on intramedullary procedures we may refer to Danckwardt Lilliestrom (1969 pp 17-22) and Danckwardt Lilliestrom et al (1970a pp 3-12).

### 2 3 1 Medullary reactions

Medullary devascularization leads to necrosis of the bone marrow. After an intramedullary procedure one initially finds a blood clot with

### 2.3.3 The periosteal reaction

The periosteal reaction of diaphyseal bone to intramedullary procedures is likewise highly typical. As described the primary reaction is an increase in the number of extraosseous vessels. These are of greater than normal luminal width, take a meandering course and extend perpendicular to the cortex. After about two weeks this vascular proliferation is most pronounced (Danckwardt Lilliestrom 1969), it diminishes after four weeks and is reduced to normal proportions after eight weeks if healing of the fracture or osteotomy can take place (Danckwardt Lilliestrom 1969, Rhinelanders 1973).

The osteogenic periosteal layer immediately shows marked cellular activity and reacts by the formation of new subperiosteal young bone. This layer of new bone may cover the entire surface of the diaphysis. Danckwardt Lilliestrom (1969) distinguished two morphological types: a thinner layer of lamellar bone and a thicker layer of woven trabecular bone with its trabeculae perpendicular to the cortex. Cartilage is found only at sites directly adjacent to an osteotomy or shaft fracture (i.e. never beneath intact periosteum). This formation of new bone usually attains its maximum after two to three weeks (Trueta & Cavadas 1955, Richany et al. 1965, Danckwardt Lilliestrom 1969). In the course of subsequent weeks this young trabecular bone is gradually replaced by lamellar bone, and the demarcation between the old cortex and the new subperiosteal layer is effaced. At the same time normalization of the extraosseous vascular reaction is observed.

Radiologically the new bone initially has a cloudy appearance but eventually the structure becomes denser and the entire cortex proves to have increased in diameter (Trueta & Cavadas 1954, Huntischer 1962, Slooff 1970, Lindwer 1972, Rhinelanders 1973). An exception is the experimental work of Gothman (1960b) who, after insertion of an intramedullary nail in mature rabbit tibiae, observed periosteal hyperplasia in only a few instances and subperiosteal bone apposition in none in spite of marked extraosseous vascular proliferation. Periosteal new bone formation has been given a variety of names. Such designations as subperiosteal reaction (Richany et al. 1965, Danckwardt Lilliestrom 1969), periosteal apposition (Lindwer 1972), provisional callus (Huntischer 1940), external callus (Rhinelanders 1973), new cortex (Anderson 1965, Danckwardt Lilliestrom et al. 1970a) and secondary cortex (Slooff 1970) all refer to the same phenomenon.

The diameter of the new bone layer can be quite considerable. This too depends on the severity of the lesion and on the age and species of the test animal used. An interesting fact in this context is the similarity reported by Richany et al. (1965) and Kelly (1968a, 1968b) to the periosteal bone apposition seen in the long bones in pulmonary hyper-

disappeared, and one third to two thirds of the inner cortex has become necrotic (Trueta & Cavadias 1955, 1964, Richany et al 1965, Danckwardt Lilliestrom 1969) In these areas the bone lacunae are empty After a while the Haversian canals and the bone lacunae dilate, and after two weeks the partial cortical necrosis attains its maximum (Trueta & Cavadias 1964, Richany et al 1965, Danckwardt Lilliestrom 1969)

As described in the first section of this chapter, extraosseous vessels react by a very marked proliferation and increase in luminal width, and such investigators as Danckwardt Lilliestrom (1969) have demonstrated this within 24 hours Soon after, new blood vessels are observed, which penetrate the cortex from the periphery and eventually also from the medullary cavity With these new vessels many 'bone forming cells' appear (Brookes 1971) Although one might expect predominance of degradation of necrotic tissue in the early stages, yet few osteoclasts are observed (e.g. Brookes 1960b)

Large resorption lacunae appear, first in the middle one third of the cortex and then gradually also further down where the necrosis is deepest In the inner cortex these lacunae come to occupy so much space that fragments of dead endosteal bone can be rejected as sequestra into the medullary cavity (Trueta & Cavadias 1955, 1964 Danckwardt Lilliestrom et al 1970a, Slooff 1970, Lindwer 1972) Large vascular spaces, sometimes filled with bone marrow, are left behind in the inner part of the cortex (Brookes 1960, Richany et al 1965 Slooff 1970 Rhinelander 1973) These spaces produce the radiological features of osteoporosis (Brookes 1960, Rhinelander 1973) Brookes (1960) refers to this process as 'medullization' and Slooff (1970) speaks of 'spongification' of the cortex

It should once again be clearly emphasized that the development of all these changes largely depends on the severity of ischaemia New endosteum begins to form after about six weeks (Richany et al 1965, Slooff 1970, Rhinelander 1973) and from this a new endosteal layer of lamellar bone is deposited At about the same time the process of resorption of dead cortical bone also attains its maximum intensity (Richany et al 1965, Danckwardt Lilliestrom 1969) According to Danckwardt Lilliestrom (1969 1970) bone remodelling takes place by infiltration of large broom shaped bundles of blood vessels which anastomose with pre-existent intracortical vessels and of vessels preceded by osteoclasts so called cutter heads (Schenk & Willenegger 1963) Even though the majority of investigators report complete revascularization after about eight weeks, necrotic areas can be encountered even after many months (Foster et al 1951 Trueta & Cavadias 1955 Gustilo et al 1964, Richany et al 1965 Slooff 1970) to years (Lindwer 1972) This applies in particular to older animals in which the stimulus to recovery appears to become exhausted (Trueta 1968)

### 2.3.3 The periosteal reaction

The periosteal reaction of diaphyseal bone to intramedullary procedures is likewise highly typical. As described the primary reaction is an increase in the number of extraosseous vessels. These are of greater than normal luminal width, take a meandering course and extend perpendicular to the cortex. After about two weeks this vascular proliferation is most pronounced (Danckwardt Lilliestrom 1969), it diminishes after four weeks and is reduced to normal proportions after eight weeks if healing of the fracture or osteotomy can take place (Danckwardt Lilliestrom 1969, Rhinelander 1973).

The osteogenic periosteal layer immediately shows marked cellular activity and reacts by the formation of new subperiosteal young bone. This layer of new bone may cover the entire surface of the diaphysis. Danckwardt Lilliestrom (1969) distinguished two morphological types: a thinner layer of lamellar bone and a thicker layer of woven trabecular bone with its trabeculae perpendicular to the cortex. Cartilage is found only at sites directly adjacent to an osteotomy or shaft fracture (i.e. never beneath intact periosteum). This formation of new bone usually attains its maximum after two to three weeks (Trueta & Cavadias 1955, Richany et al. 1965, Danckwardt Lilliestrom 1969). In the course of subsequent weeks this young trabecular bone is gradually replaced by lamellar bone and the demarcation between the old cortex and the new subperiosteal layer is effaced. At the same time, normalization of the extraosseous vascular reaction is observed.

Radiologically the new bone initially has a cloudy appearance but eventually the structure becomes denser and the entire cortex proves to have increased in diameter (Trueta & Cavadias 1954, Kuntscher 1962, Slooff 1970, Lindwer 1972, Rhinelander 1973). An exception is the experimental work of Gothman (1960b) who after insertion of an intramedullary nail in mature rabbit tibiae observed periosteal hyperplasia in only a few instances and subperiosteal bone apposition in none in spite of marked extraosseous vascular proliferation. Periosteal new bone formation has been given a variety of names. Such designations as subperiosteal reaction (Richany et al. 1965, Danckwardt Lilliestrom 1969), periosteal apposition (Lindwer 1972), provisional callus (Kuntscher 1940), external callus (Rhinelander 1973), new cortex (Anderson 1965, Danckwardt Lilliestrom et al. 1970a) and secondary cortex (Slooff 1970) all refer to the same phenomenon.

The diameter of the new bone layer can be quite considerable. This too depends on the severity of the lesion and on the age and species of the test animal used. An interesting fact in this context is the similarity reported by Richany et al. (1965) and Kelly (1968a, 1968b) to the periosteal bone apposition seen in the long bones in pulmonary hyper-

disappeared, and one third to two thirds of the inner cortex has become necrotic (Trueta & Cavadias 1955, 1964, Richany et al 1965, Danckwardt-Lilliestrom 1969) In these areas the bone lacunae are empty After a while the Haversian canals and the bone lacunae dilate, and after two weeks the partial cortical necrosis attains its maximum (Trueta & Cavadias 1964, Richany et al 1965, Danckwardt Lilliestrom 1969)

As described in the first section of this chapter, extraosseous vessels react by a very marked proliferation and increase in luminal width, and such investigators as Danckwardt-Lilliestrom (1969) have demonstrated this within 24 hours Soon after, new blood vessels are observed, which penetrate the cortex from the periphery and eventually also from the medullary cavity With these new vessels, many „bone forming cells“ appear (Brookes 1971) Although one might expect predominance of degradation of necrotic tissue in the early stages, yet few osteoclasts are observed (e.g. Brookes 1960b)

Large resorption lacunae appear, first in the middle one third of the cortex and then gradually also further down, where the necrosis is deepest In the inner cortex these lacunae come to occupy so much space that fragments of dead endosteal bone can be rejected as sequestra into the medullary cavity (Trueta & Cavadias 1955 1964 Danckwardt-Lilliestrom et al 1970a, Slooff 1970 Lindwer 1972) Large vascular spaces, sometimes filled with bone marrow, are left behind in the inner part of the cortex (Brookes 1960, Richany et al 1965, Slooff 1970 Rhinelander 1973) These spaces produce the radiological features of osteoporosis (Brookes 1960, Rhinelander 1973) Brookes (1960) refers to this process as 'medullization' and Slooff (1970) speaks of „spongification“ of the cortex

It should once again be clearly emphasized that the development of all these changes largely depends on the severity of ischaemia New endosteum begins to form after about six weeks (Richany et al 1965 Slooff 1970 Rhinelander 1973) and from this a new endosteal layer of lamellar bone is deposited At about the same time the process of resorption of dead cortical bone also attains its maximum intensity (Richany et al 1965 Danckwardt Lilliestrom 1969) According to Danckwardt Lilliestrom (1969, 1970) bone remodelling takes place by infiltration of large broom shaped bundles of blood vessels which anastomose with pre-existent intracortical vessels and of vessels preceded by osteoclasts so called cutter heads (Schenk & Willenegger 1963) Even though the majority of investigators report complete revascularization after about eight weeks necrotic areas can be encountered even after many months (Foster et al 1951 Trueta & Cavadias 1955 Gustilo et al 1964, Richany et al 1965 Slooff 1970) to years (Lindwer 1972) This applies in particular to older animals in which the stimulus to recovery appears to become exhausted (Trueta 1968)

Although considerable research has been devoted to the physiology of the blood circulation in bone and strong indications have been found that it is regulated via neural hormonal and particularly metabolic routes the exact mechanisms which control blood flow are still unknown (Shim 1968 Kelly 1968a Sim & Kelly 1970)

### 2.3.4 Bone marrow embolism

Danckwardt Lilliestrom (1969) maintained that the ischaemia resulting from vascular interruption is alone insufficient to explain the variations in the extent of subperiosteal bone apposition and cortical necrosis which can be observed even in the same section. There should be another factor which could cause avascularity. He was the first to demonstrate that intracortical bone marrow embolisms are an important cause of the above described changes and also that they can explain the occurrence of variations within the same bone after a medullary lesion. As part of his experiment (cf page 38) he compared the percentage of avascular cortex with the amount of fat embolism demonstrated in intracortical vessels with the aid of Sudan 3 staining. He found an unmistakable correlation. He assumed that due to an increase in intramedullary pressure resulting from the intervention bone marrow was pressed into the Haversian canals and caused their obliteration. The resulting intracortical block he reasoned contributed to the extent and intensity of the cortical necrosis and the reactive subperiosteal bone formation.

Subperiosteally deposited bone marrow was also demonstrated. When the bone marrow was removed by suction through a separate aperture in the distal metaphysis thus at the same time reducing the intramedullary pressure the vascular damage to the cortex was substantially less and revascularization of the entire cortex was demonstrable four weeks after the operation (Danckwardt Lilliestrom et al 1970b).

The experience gained was confirmed in the second experiment (cf page 39). Both cortical necrosis and subperiosteal bone formation were substantially reduced after reducing the intramedullary pressure and removal of the bone marrow by suction. It was also found that consolidation of the osteotomy was considerably quicker when the intracortical circulation was not blocked by fat embolism.

The occurrence of fat embolism following intramedullary procedures is not confined to the osteotomized bone. Olcrud et al (1969) found massive fat emboli in the femoral vein after reaming a rabbit tibia. In the second experiment of Danckwardt Lilliestrom et al (1970a) described on page 39 the mortality due to pulmonary fat emboli was 11 per cent in the non-suction group and 10 per cent of the animals showed unmistakable signs of systemic fat emboli but survived.

trophy osteoarthropathy Although vascular changes are probably the substrate of this symptom, the exact aetiological mechanism has so far remained obscure (Lipman & Massie 1964)

Several explanations have been suggested for the newly formed subperiosteal bone after intramedullary interventions

- 1 It has been ascribed to chemical or physical irritation caused by the material of the intramedullary nail (Kuntscher 1940 1962) or to pressure exerted by the nail on the bone, or it has been regarded as a reaction to insufficient fixation of the bone fragments by the nail (L & J Bohler 1949)
- 2 Such investigators as Vanderhoeft et al (1963) reported periosteal bone apposition distal to an artificial arteriovenous fistula in growing dogs They were unable to offer an explanation
- 3 Richany et al (1965) contemplated the possibility of stasis and oedema, leading to local anoxia and prompting the formation of new bone
- 4 Zucman et al (1968) found bone marrow subperiosteally after reaming of rabbit tibiae and believed that this marrow, pressed through the cortical canals, could promote callus formation in the manner of an autograft
- 5 Kelly (1968b) produced periosteal tibial bone formation by placing a tourniquet around a thigh in growing dogs He observed increased pressure in the lateral saphenous vein and accelerated flow (clearance of  $^{86}\text{Sr}$ ) in the tibia He regarded increased pressure in veins and capillaries as the cause of the formation of a new layer of subperiosteal bone
- 6 Trueta & Cavadias (1955, 1964), who pointed out the prominent role of the medullary circulation in the blood supply to the cortex, sought the primary cause in the ischaemia caused by intramedullary procedures, which provokes proliferation of periosteal vessels with accompanying new bone formation Koenberg (1963) also believed that the cause was to be found in interruption of the circulation Brookes (1971, p 242) likewise believed the ischaemia to be the causative factor, and he made special mention of the changed intravascular pressure relations Local periosteal hyperaemia could be followed by an increased cortical flow rate and changes in local oxygen and carbon dioxide pressures

As Sim & Kelly (1970) pointed out, the oxygen demand at a local metabolic level could be an important factor in blood flow regulation

Although considerable research has been devoted to the physiology of the blood circulation in bone and strong indications have been found that it is regulated via neural hormonal and particularly metabolic routes the exact mechanisms which control blood flow are still unknown (Shim 1968 Kelly 1968a Sim & Kelly 1970)

#### 2.3.4 Bone marrow embolism

Danckwardt Lilliestrom (1969) maintained that the ischaemia resulting from vascular interruption is alone insufficient to explain the variations in the extent of subperiosteal bone apposition and cortical necrosis which can be observed even in the same section. There should be another factor which could cause avascularity. He was the first to demonstrate that intracortical bone marrow embolisms are an important cause of the above described changes and also that they can explain the occurrence of variations within the same bone after a medullary lesion. As part of his experiment (cf page 38) he compared the percentage of avascular cortex with the amount of fat embolism demonstrated in intracortical vessels with the aid of Sudan 3 staining. He found an unmistakable correlation. He assumed that due to an increase in intramedullary pressure resulting from the intervention bone marrow was pressed into the Haversian canals and caused their obliteration. The resulting intracortical block, he reasoned, contributed to the extent and intensity of the cortical necrosis and the reactive subperiosteal bone formation.

Subperiosteally deposited bone marrow was also demonstrated. When the bone marrow was removed by suction through a separate aperture in the distal metaphysis thus at the same time reducing the intramedullary pressure the vascular damage to the cortex was substantially less and revascularization of the entire cortex was demonstrable four weeks after the operation (Danckwardt Lilliestrom et al 1970b).

The experience gained was confirmed in the second experiment (cf page 39). Both cortical necrosis and subperiosteal bone formation were substantially reduced after reducing the intramedullary pressure and removal of the bone marrow by suction. It was also found that consolidation of the osteotomy was considerably quicker when the intracortical circulation was not blocked by fat embolism.

The occurrence of fat embolism following intramedullary procedures is not confined to the osteotomized bone. Olerud et al (1969) found massive fat emboli in the femoral vein after reaming a rabbit tibia. In the second experiment of Danckwardt Lilliestrom et al (1970a) described on page 39 the mortality due to pulmonary fat emboli was 11 per cent in the non suction group and 10 per cent of the animals showed unmistakable signs of systemic fat emboli, but survived.

trophic osteoarthropathy Although vascular changes are probably the substrate of this symptom, the exact aetiological mechanism has so far remained obscure (Lipman & Massie 1964)

Several explanations have been suggested for the newly formed subperiosteal bone after intramedullary interventions

- 1 It has been ascribed to *chemical or physical irritation* caused by the material of the intramedullary nail (Kuntscher 1940, 1962) or to pressure exerted by the nail on the bone, or it has been regarded as a reaction to *insufficient fixation of the bone fragments* by the nail (L. & J. Bohler 1949)
- 2 Such investigators as Vanderhoeft et al (1963) reported periosteal bone apposition distal to an artificial arteriovenous fistula in growing dogs They were unable to offer an explanation
- 3 Richany et al (1965) contemplated the possibility of stasis and oedema, leading to local anoxia and prompting the formation of new bone
- 4 Zucman et al (1968) found bone marrow subperiosteally after reaming of rabbit tibiae and believed that this marrow, pressed through the cortical canals could promote callus formation in the manner of an autograft
- 5 Kelly (1968b) produced periosteal tibial bone formation by placing a tourniquet around a thigh in growing dogs He observed increased pressure in the lateral saphenous vein and accelerated flow (clearance of  $^{85}\text{Sr}$ ) in the tibia He regarded increased pressure in veins and capillaries as the cause of the formation of a new layer of subperiosteal bone
- 6 Trueta & Cavadias (1955, 1964), who pointed out the prominent role of the medullary circulation in the blood supply to the cortex, sought the primary cause in the ischaemia caused by intramedullary procedures, which provokes proliferation of periosteal vessels with accompanying new bone formation Koenkenberg (1963) also believed that the cause was to be found in interruption of the circulation Brookes (1971, p. 242) likewise believed the ischaemia to be the causative factor, and he made special mention of the changed intravascular pressure relations Local periosteal hyperaemia could be followed by an increased cortical flow rate and changes in local oxygen and carbon dioxide pressures

As Sim & Kelly (1970) pointed out the oxygen demand at a local metabolic level could be an important factor in blood flow regulation

and, depending on the severity of the ischaemia produced this necrosis can involve almost the entire cortex. The avascular bone marrow also becomes necrotic.

During the repair phase the medullary circulation proves to have enormous regenerative powers and after a while it can entirely resume its function in the cortical blood supply. This concludes the importance of the temporary extraosseous vessels as a collateral system and the rapid formation of young bone likewise subsides. This subperiosteal bone layer matures and is partially incorporated in the old cortex. In the cortex dead bone is resorbed through invasion of new vessels and replaced by new bone. For instance a newly formed endosteum deposits a layer of lamellar bone. This process can take a very long time and is associated with the formation of large vascular spaces which may contain bone marrow and with sequestration of necrotic endosteal bone to the medullary cavity. During the reorganization of the bone marrow after reaming macrophages and giant cells may be strikingly numerous. Also scattered spicules of bone may form centrally in the medullary cavity to be eventually resorbed.

Finally it has been found that an intramedullary procedure can lead to systemic fat or bone marrow embolism as a result of a local increase in pressure.

The possible correlation between high intramedullary pressure and pulmonary fat embolism has also forcefully come to the fore in a different context. Postmortems on patients who had died of acute cardiac arrest during a total hip or knee arthroplasty or hemiarthroplasty of the hip in which bone cement was used, revealed massive fat and bone marrow embolism in the lungs (Milne 1973, Dandy 1974, Herndon et al 1974).

This was initially interpreted as a possible side effect of the acrylic cement used, and special importance was attached in this respect to the lipophilic monomer (page 21).

Recent animal experiments carried out by Kallos et al (1974b) have confirmed, however, that the occurrence of pulmonary bone marrow emboli is a direct result of an increase in intramedullary pressure. No effort was made to establish the extent to which acrylic cement constituents too, may influence the occurrence of fat embolism (cf. page 62).

## 2.4 Summary

Under physiological conditions the arterial afferent vascularization of the diaphyseal cortex of a long bone is dependent on the medullary circulation. This is supplied by the nutrient artery (arteries) and in part by anastomoses with the metaphyseal arterial system. The flow is centrifugal. The periosteal vessels are thought to be of subordinate importance in this vascularization, only a small outer cortical sector near the sites of muscle attachment (linea aspera of femur) being supplied by periosteal vessels.

Intramedullary procedures interfere with this pattern. Depending on the severity of the lesion involved, the endosteal circulation is partly or totally interrupted thus depriving the cortical bone of its principal source of blood supply. Moreover, the cortical ischaemia is also in part determined by the occurrence of intracortical bone marrow emboli. These are as much more numerous as the intramedullary pressure during the intervention is higher (Danckwardt Lilliestrom and co workers). The reaction pattern of, in succession the diaphyseal cortical circulation, the periosteum, the cortex and the medullary cavity is characteristic and reproducible. It is largely dependent, however, on the severity of the lesion, the increase in intramedullary pressure involved, the animal species used and the age of the animal.

To some extent the extraosseous circulation of healing bone is capable of taking over the circulation in the diaphyseal cortex. The afferent flow becomes temporarily centripetal. Proliferation of the extraosseous vessels is accompanied by the formation of a subperiosteal layer of young bone over the entire cortical surface. The inner cortical layers become necrotic.

and depending on the severity of the ischaemia produced this necrosis can involve almost the entire cortex. The avascular bone marrow also becomes necrotic.

During the repair phase the medullary circulation proves to have enormous regenerative powers and after a while it can entirely resume its function in the cortical blood supply. This concludes the importance of the temporary extraosseous vessels as a collateral system and the rapid formation of young bone likewise subsides. This subperiosteal bone layer matures and is partially incorporated in the old cortex. In the cortex dead bone is resorbed through invasion of new vessels and replaced by new bone. For instance a newly formed endosteum deposits a layer of lamellar bone. This process can take a very long time and is associated with the formation of large vascular spaces which may contain bone marrow and with sequestration of necrotic endosteal bone to the medullary cavity. During the reorganization of the bone marrow after reaming, macrophages and giant cells may be strikingly numerous. Also scattered spicules of bone may form centrally in the medullary cavity to be eventually resorbed.

Finally it has been found that an intramedullary procedure can lead to systemic fat or bone marrow embolism as a result of a local increase in pressure.

The possible correlation between high intramedullary pressure and pulmonary fat embolism has also forcefully come to the fore in a different context. Postmortems on patients who had died of acute cardiac arrest during a total hip or knee arthroplasty or hemiarthroplasty of the hip in which bone cement was used, revealed massive fat and bone marrow embolism in the lungs (Milne 1973, Dandy 1974, Herndon et al 1974).

This was initially interpreted as a possible side effect of the acrylic cement used, and special importance was attached in this respect to the lipophilic monomer (page 21).

Recent animal experiments carried out by Kallos et al (1974b) have confirmed, however, that the occurrence of pulmonary bone marrow emboli is a direct result of an increase in intramedullary pressure. No effort was made to establish the extent to which acrylic cement constituents too, may influence the occurrence of fat embolism (cf. page 62).

## 2.4 Summary

Under physiological conditions the arterial afferent vascularization of the diaphyseal cortex of a long bone is dependent on the medullary circulation. This is supplied by the nutrient artery (arteries), and in part by anastomoses with the metaphyseal arterial system. The flow is centrifugal. The periosteal vessels are thought to be of subordinate importance in this vascularization, only a small outer cortical sector near the sites of muscle attachment (linea aspera of femur) being supplied by periosteal vessels.

Intramedullary procedures interfere with this pattern. Depending on the severity of the lesion involved, the endosteal circulation is partly or totally interrupted, thus depriving the cortical bone of its principal source of blood supply. Moreover, the cortical ischaemia is also in part determined by the occurrence of intracortical bone marrow emboli. These are as much more numerous as the intramedullary pressure during the intervention is higher (Danckwardt Lilliestrom and co workers). The reaction pattern of in succession the diaphyseal cortical circulation, the periosteum, the cortex and the medullary cavity is characteristic and reproducible. It is largely dependent, however, on the severity of the lesion, the increase in intramedullary pressure involved, the animal species used and the age of the animal.

To some extent the extraosseous circulation of healing bone is capable of taking over the circulation in the diaphyseal cortex. The afferent flow becomes temporarily centripetal. Proliferation of the extraosseous vessels is accompanied by the formation of a subperiosteal layer of young bone over the entire cortical surface. The inner cortical layers become necrotic.

and depending on the severity of the ischaemia produced this necrosis can involve almost the entire cortex. The avascular bone marrow also becomes necrotic.

During the repair phase the medullary circulation proves to have enormous regenerative powers and after a while it can entirely resume its function in the cortical blood supply. This concludes the importance of the temporary extraosseous vessels as a collateral system and the rapid formation of young bone likewise subsides. This subperiosteal bone layer matures and is partially incorporated in the old cortex. In the cortex dead bone is resorbed through invasion of new vessels and replaced by new bone. For instance a newly formed endosteum deposits a layer of lamellar bone. This process can take a very long time and is associated with the formation of large vascular spaces which may contain bone marrow and with sequestration of necrotic endosteal bone to the medullary cavity. During the reorganization of the bone marrow after reaming macrophages and giant cells may be strikingly numerous. Also scattered spicules of bone may form centrally in the medullary cavity to be eventually resorbed.

Finally it has been found that an intramedullary procedure can lead to systemic fat or bone marrow embolism as a result of a local increase in pressure.

## CHAPTER 3

### DESCRIPTION OF THE EXPERIMENT

#### 3.1 *Objective, argumentation and design*

The objective of the investigation to be described was to establish, on the basis of animal experiments, which local side effects of acrylic cement cause the histological changes in cortical bone

In the analysis of these side effects of acrylic cement, they had to be distinguished from the reactions which occur in cortical bone after interruption of the medullary vascularization, as described in chapter 2

To begin with, the effect of interference with the medullary vascularization had to be studied in the model chosen for this study the rabbit femur Next it had to be established which histological changes occur in cortical bone when acrylic cement is implanted in addition For this purpose the two principal local side effects – those of the high polymerization temperature and the cytotoxicity of the monomer – had to be separately compared with the tissue reactions caused by interruption of the medullary vascularization

For a separate study of the high temperature effect we had to look for an acrylic cement which showed no or only a negligible rise in temperature at a constant monomer content The effect of this cement had then to be compared with the reactions caused in bone by commercial acrylic cement A simple subtraction would then give the tissue damage due to the effect of the high maximum polymerization temperature

For a separate study of the monomer effect an acrylic cement had to be found which contained a monomer excess but showed no rise in temperature For this too we had to establish the extra effect in tissue damage besides the effect of interruption of the medullary vascularization The reactions thus obtained had then to be compared with those produced by cement with a low maximum polymerization temperature and a normal monomer content

A supplementary study had to be made of the additional deleterious effect of monomer leaking from set cement (so called residual monomer 2-5 per cent which remains in cured PMMA page 21) The results thus obtained had to be compared with those produced solely by interruption of the medullary vascularization

In this manner it was argued it would be possible to gain from the rabbit femur an impression of which reactions in diaphyseal cortical bone are caused by

- 1 interruption of the medullary vascularization
- 2 cytotoxicity of an overdose of monomer
- 3 cytotoxicity of a very small amount of monomer which leaks from a set cement mass
- 4 high polymerization temperature of acrylic cement setting in situ

In order to separate these four effects different cement types were used (section 3.2). The test animals used in this study (section 3.3) were divided into seven different groups (section 3.6) after the operation (section 3.4).

In order to study the changes in the vascularization of diaphyseal cortical bone the lower limbs of the test animals were perfused with a fine granular barium sulphate suspension after sacrifice (section 3.7). Vascularization patterns were studied radiologically (section 3.8) and microangiographically (section 3.10).

The histopathological changes of cortical bone were studied after processing the femurs for histological (section 3.9) fluorescence microscopic (section 3.11) and autoradiographic (section 3.12) examination.

## 3.2 Cement types

Three types of cement\* were used in the experiment

- a commercial acrylic cement (Palacos and Sulfix 6)
- b a catalyst free acrylic cement obtained from one of the commercial plastics (Palacos and Sulfix-6)
- c a modified acrylic cement (Sulfix-6 with CMC gel)

### 3.2.1 Palacos and Sulfix 6

The properties of Palacos which has been used in Europe for many years can be presumed known. The ratio polymer powder with radiopaque contrast medium monomer fluid is 2:1. The conventional packings contain about 40 g powder and 20 ml fluid.

\*Palacos® and Sulfix® were respectively supplied by Kulzer & Co GmbH 638 Bad Homburg v.d.H., Germany and Sulzer Bro Ltd, -CH-840 Winterthur Switzerland.

Sulfix-6 is a new commercial product described by the manufacturer as different from products marketed earlier (Palacos, CMW and Simplex P) in that it has a number of improved properties. It is somewhat more finely granular and has a longer working time (Debrunner and Wettstein 1975a), because 15 per cent of the fluid consists of the copolymer *n* butylmethacrylate, there is an indication of a (not significantly) lower maximum polymerization temperature at the cement surface (Debrunner 1974), and its lower porosity (Semlitsch 1975) is believed to give it slightly better mechanical properties than the other commercial acrylic cements. There are no differences in monomer release (Debrunner and Wettstein 1975b), tissue toxicity of the cured product (Semlitsch 1973) and volumetric changes during polymerization (Debrunner 1975). As in Palacos, zirconium dioxide has been added to the polymer powder as radiopaque contrast medium. The ratio polymer powder : monomer fluid is 5 : 2. Conventional packings contain 40 g powder and 16 ml fluid.

### 3.2.2 Catalyst free „acrylic cement”

As described in section 1 of chapter 1, polymerization occurs by virtue of the presence of an initiator in the powder and an activator in the fluid. When the benzoyl peroxide (initiator) is washed out with methanol, no polymerization reaction occurs: the end product becomes neither warm nor hard. One obtains a rubber-like substance which remains malleable for days but, exposed to air, sets after about a week due to evaporation of the monomer, this is accompanied by an unmistakable decrease in volume. We had the disposal of polymer powder and monomer fluid without catalyst system. Since no polymerization takes place in this „cement”, an overdose of monomer remains in it (about 30 volume per cent). By eliminating the high polymerization temperature we could separately study the cytotoxic effect of this excess of monomer.

### 3.2.3 Modified acrylic cement Sulfix 6 with CMC gel\*

Next we looked for a cement which would enable us to eliminate the factor polymerization temperature. Initially we succeeded in reducing the maximum polymerization temperature by adding water when mixing the cement. Due to phase separation, however, no homogeneous distribution of water and cement could be obtained. Moreover, the mixture could not be used in the syringe. By using a high viscosity gel J. R. de Wijn Chem. E. (Department of Dental Materials, Nijmegen University)

Fig 4 Arrangement for measuring the maximum temperature in polymerizing cements

succeeded in reducing the maximum temperature without affecting the manageability of the mixture

To the Sulfix 6 powder and fluid in the ratio indicated by the manufacturer an amount of high viscosity CMC gel was added to make a mixture with 36.5 per cent (weight) gel. The polymer powder : CMC gel : monomer fluid ratio was 5 : 4 : 2. Gel phase and resin phase in this mixture remained well distributed which is to say that the gel formed a smooth outer layer on the surface.

In the centre of a test rod (fig 4) of 0.5 cu cm the maximum polymerization temperature of this cement remained between 50° and 60° C. In a similar test rod the commercial cement attained a temperature of 80-100° C (fig 5). In a globule of CMC cement kept in the hand, hardly any rise in temperature could be felt and the temperature *in vivo* could be expected to be even lower because of the favourable heat release at the cement/bone interface (Debrunner 1975, Biehl et al 1974). There were therefore sound reasons to presume that the temperature effect had been drastically reduced.

It was likewise to be expected that the percentage of nonpolymerizing monomer would equal or slightly exceed (due to the low polymerization temperature) that in the conventional commercial bone cements.

The biphasic mixture of gel and cement will develop what may be described as a gel filled porosity and this of course influences the mechanical properties also. Since the aqueous gel phase is biodegradable (dissolves) it could be maintained that a porous cement had been ob-

Sulfix-6 is a new commercial product described by the manufacturer as different from products marketed earlier (Palacos, CMW and Simplex P) in that it has a number of improved properties. It is somewhat more finely granular and has a longer working time (Debrunner and Wittstein 1975a), because 15 per cent of the fluid consists of the copolymer n butylmethacrylate, there is an indication of a (not significantly) lower maximum polymerization temperature at the cement surface (Debrunner 1974), and its lower porosity (Semlitsch 1975) is believed to give it slightly better mechanical properties than the other commercial acrylic cements. There are no differences in monomer release (Debrunner and Wittstein 1975b), tissue toxicity of the cured product (Semlitsch 1973) and volumetric changes during polymerization (Debrunner 1975). As in Palacos, zirconium dioxide has been added to the polymer powder as radiopaque contrast medium. The ratio polymer powder : monomer fluid is 5:2. Conventional packings contain 40 g powder and 16 ml fluid.

### 3.2.2 Catalyst free „acrylic cement“

As described in section 1 of chapter 1, polymerization occurs by virtue of the presence of an initiator in the powder and an activator in the fluid. When the benzoyl peroxide (initiator) is washed out with methanol no polymerization reaction occurs: the end product becomes neither warm nor hard. One obtains a rubber-like substance which remains malleable for days but, exposed to air, sets after about a week due to evaporation of the monomer, this is accompanied by an unmistakable decrease in volume. We had the disposal of polymer powder and monomer fluid without catalyst system. Since no polymerization takes place in this „cement“, an overdose of monomer remains in it (about 30 volume per cent). By eliminating the high polymerization temperature we could separately study the cytotoxic effect of this excess of monomer.

### 3.2.3 Modified acrylic cement Sulfix 6 with CMC gel\*

Next we looked for a cement which would enable us to eliminate the factor polymerization temperature. Initially we succeeded in reducing the maximum polymerization temperature by adding water when mixing the cement. Due to phase separation however no homogeneous distribution of water and cement could be obtained. Moreover, the mixture could not be used in the syringe. By using a high viscosity gel J. R. de Wijn Chem. E. (Department of Dental Materials Nijmegen University)

Fig 5 General shape of temperature time curve in laboratory tests The polymerization time is the same for both types of cement

tained! The pores communicated and so formed a system with so called open porosity, in contrast with the closed porosity of commercial acrylic cements (fig 6) Porous implant materials, with all their advantages and disadvantages are currently in the centre of interest For a brief discussion we refer to chapter 5 For the design of this study it was of primary importance that a manageable cement was obtained in which the high maximum polymerization temperature was eliminated while the percent age of non polymerizing monomer remained about the same

The gel was a solution of 5 per cent sodium carboxymethylcellulose (CMC)\* in water A 1 per cent aqueous solution of this CMC has a viscosity of 400 centipoise (CPs) The viscosity of the 5 per cent CMC gel used as measured with a Brookfield viscosimeter at 3 rpm was about 120 000 CPs

Carboxymethylcellulose is extensively used in the foods industry as wallpapering glue in rayon yarns and as constituent of synthetic detergents In pharmacology it is used as adjuvant in oral preparations and eye lotions and as catheter lubricant So far as could be established its toxicity to vascularized tissues is negligible

### 3 2 4 Sterilization

The polymer powder received from the manufacturer in the unsterilized form (Palacos and Sulfix) was divided into 10 g fractions which

were double packed and gas sterilized (ethylene oxide) In view of the toxicity of ethylene oxide (O'Leary and Guess 1968), the sterilized powder was not permitted to be used until 2 x 24 hours after sterilization (O'Leary et al 1968, Zagar 1972) No bacterial growth was ever found in samples which were bacteriologically examined The monomer fluid supplied by the manufacturer was sterile, and was divided into pre sterilized bottles under aseptic precautions The amounts for Palacos and Sulfix 6 were 5 ml and 4 ml, respectively

The CMC solution in water was sterilized in saturated water vapour at 100° C in a glass jar for 30 minutes and then, in a semi liquid state divided into sterilized eye ointment tubes under aseptic precautions Because the viscosity diminished during sterilization due to thermic degradation of the CMC polymer (breakdown of chain length) we used a high viscosity CMC sodium gel to start with This ensured that the product obtained after ultimate mixing with Sulfix 6 had the desired consistency

### 3.3 Test animals

The test animals used in the experiment were 166 young adult rabbits of the New-Zealand White strain They were selected because a large number of animals were needed and because adequate data are available on the vascularization of the rabbit femur The animals were about 4 months old, in good health, averaging 2465 g (range 1900-3400 g) body weight immediately before operation All were obtained from the same breeder and arrived at the animal laboratory at least 14 days before being used in the experiment They were accommodated in individual cages with grid floor, received water *ad libitum* and were fed a standard diet (standard mixture L K = 01 Hopefarms n v Woerden, Netherlands)

The rabbits were randomly taken from the various litters and divided over the various groups (section 3.6) The sex distribution was likewise at random

In 4 month old rabbits the growth plates have not yet closed The expected total longitudinal growth of the average rabbit femur is indicated in fig. 7 The curve shown corresponds with the longitudinal growth pattern of the rabbit tibia indicated by Heikel (1960) in which the initially linear growth curve likewise declines after 100 days

### 3.4 Operative technique

The animals were fasted during 24 hours preceding the operation Anaesthesia was induced by intravenous injection of 0.5 mg atropine and 30 mg/kg pentobarbital sodium (Nembutal S A Abbott n v Amster

**Fig 7** Longitudinal growth curves of the rabbit femur. At age 6 8 10 12 14 16 18 20 22 26 28 34 and 36 weeks, X ray were made of both femurs in a measuring box especially designed for this purpose under general anaesthesia. In this box the distances between focus and plate (66.5 cm) and between femur and plate (5.7 cm) remained constant. On an OPTOCOM measuring table the coordinates (most distal end of lateral femur and most proximal end of greater trochanter) were established, where upon the computer calculated the distances and plotted the mean curve for both femurs of 5 male (top curve) and 5 female (bottom curve) New Zealand White rabbits. For calculation of the true femoral lengths, the values indicated in the two curves must be corrected by factor 0.914 (from a doctoral thesis by H. M. van de Sandt: Circumferential sectioning of the periosteum in press).

dam) At the same time each animal received 50 mg/kg oxytetracycline (Terramycin Pfizer Ltd Sandwich England) by intravenous injection as fluorochrome.

After intubation the entire left hindleg was shaved and washed with Bethadine iodine soap and 70 per cent alcohol. The animal was put on the table on its right side lying on a water heated mat and connected to a Heuskamp Amsterdam Infant Ventilator for ventilation with a mixture of oxygen and nitrous oxide (ratio 1:2) and 1 per cent halothane (Fluothane).

Sterility was ensured by observing precautions normally taken for any surgical intervention. The left thigh was painted with iodine and after sterile

were double packed and gas sterilized (ethylene oxide). In view of the toxicity of ethylene oxide (O Leary and Guess 1968), the sterilized powder was not permitted to be used until 2 x 24 hours after sterilization (O Leary et al 1968, Zagar 1972). No bacterial growth was ever found in samples which were bacteriologically examined. The monomer fluid supplied by the manufacturer was sterile, and was divided into pre-sterilized bottles under aseptic precautions. The amounts for Palfacos and Sulfix 6 were 5 ml and 4 ml, respectively.

The CMC solution in water was sterilized in saturated water vapour at 100° C in a glass jar for 30 minutes and then, in a semi liquid state divided into sterilized eye-ointment tubes under aseptic precautions. Because the viscosity diminished during sterilization due to thermic degradation of the CMC polymer (breakdown of chain length), we used a high-viscosity CMC sodium gel to start with. This ensured that the product obtained after ultimate mixing with Sulfix 6 had the desired consistency.

### 3.3 Test animals

The test animals used in the experiment were 166 young adult rabbits of the New-Zealand White strain. They were selected because a large number of animals were needed and because adequate data are available on the vascularization of the rabbit femur. The animals were about 4 months old, in good health, averaging 2465 g (range 1900-3400 g) body weight immediately before operation. All were obtained from the same breeder and arrived at the animal laboratory at least 14 days before being used in the experiment. They were accommodated in individual cages with grid floor, received water *ad libitum* and were fed a standard diet (standard mixture LK = 01 Hopefarms n.v., Woerden, Netherlands).

The rabbits were randomly taken from the various litters and divided over the various groups (section 3.6). The sex distribution was likewise at random.

In 4 month-old rabbits the growth plates have not yet closed. The expected total longitudinal growth of the average rabbit femur is indicated in fig. 7. The curve shown corresponds with the longitudinal growth pattern of the rabbit tibia indicated by Heikel (1960) in which the initially linear growth curve likewise declines after 100 days.

### 3.4 Operative technique

The animals were fasted during 24 hours preceding the operation. Anaesthesia was induced by intravenous injection of 0.5 mg atropine and 30 mg/kg pentobarbital sodium (Nembutal S.A. Abbott n.v. Amster-

**Fig 8** Schematic representation of the modified Impregum® syringe for cementing the medullary cavity. Screw spindle (1) with piston (2). Cap (4) with bayonet joint fitting the cylinder (3). of monomer evaporating slowly in small amounts of set acrylic cement could thus be studied. The operation was completed as indicated sub a).

- c. **Cementing of the medullary cavity.** Bone cement (cf section 3.2) was prepared and in a dough like state pressed into a modified Impregum® syringe (ESPE GmbH Seefeld Austria). The syringe had been modified (fig. 8) to correspond with the cement syringe designed for hip surgery by Slooff (1969-1970). Syringe and Teflon tubing could be sterilized. With the aid of a filler ring and plastic piston the cement was pressed into the cylinder until this was three-quarters full. The syringe was then mounted and the screw spindle tightened until the acrylic cement emerged from the end of the tubing. At that time the suction tube was replaced by the Teflon tubing of the cement syringe which was inserted into the medullary cavity as far as the femoral condyles. Slowly rotating the syringe the entire medullary cavity was filled from the distal to the proximal end while at the same time the syringe was slowly retracted. This did not require much force because the tubing was pushed proximally by the cement filling the femur (fig. 9). Usually a thin trickle of cement escaped from the vent hole and remnants of bone marrow (if any) escaped with it. The insertion and filling were done slowly so that it took about 1 minute for the femur to be filled entirely. Dependent on the size of the animal the amount of cement introduced was 2-3 ml. During this phase of the operation care was taken to ensure that the anaesthetic

draping, an incision of 1-2 cm was made over the greater trochanter. This was stripped of its periosteum, and a manual drill with a diameter of 3.2 mm was then used for cautious reaming of the medullary cavity.\* The drill was introduced over a distance of 3 cm, whereupon the correct direction was determined with a guide-wire. Drilling was then continued as far as the femoral condyles. The medullary cavity was further widened with the aid of a second manual drill with a diameter of 4.0 mm. Owing to the physiological antecurvature of the femur, reaming with this straight drill was possible only to about halfway the medullary cavity. It was needed, however, because otherwise the Teflon tubing used for suction and cementing could not be readily inserted as far as the knee. Via a second incision of 1 cm immediately proximal to the lateral femoral condyle, the periosteum was opened by means of a small longitudinal incision, the capsule was slightly pushed back and a burr hole was drilled in the cortex with a manual drill (burr diameter 1.6 mm).

A length of strong Teflon tubing (external diameter 4 mm, internal diameter 2 mm) was then inserted into the medullary cavity from the proximal end, connected with a suction tube and slowly pushed down as far as the knee. The diameter of this tubing was such that some pressure was required to insert it and it was felt to scrape along the wall of the medullary cavity. The tubing pushed most of the bone marrow away in front of it and this escaped through the vent near the lateral femoral condyle. Bone marrow remnants were sucked away by moving the Teflon tubing up and down five times until only clear blood was being sucked up. After reaming and suction of the medullary cavity the operation was continued in one of the following three ways:

- a *Closure* Fascia and skin of both incisions were closed with linen sutures while the animal was recovering from the anaesthesia. After detubation the animal was placed on a blanket near a radiator in order to prevent heat loss.
- b *Insertion of a loose fitting intramedullary rod* (Palacos®) A Palacos rod (diameter 3-4 mm, length 6.7 cm) was inserted from the proximal end and pushed in as far as the femoral condyles. Any part still protruding was cut off with bone forceps. The rods had been fashioned under sterile precautions a few hours earlier and had been kept sterile. They could be expected to contain 2.5 per cent residual monomer (Smith and Barnes 1956; Kutzner et al. 1974a). The possible tissue damaging effect

---

\* The use of a powered drill was deliberately avoided because thermic damage cannot be excluded with any certainty (Dan. Lwardt Liljestrom 1969; Matthews and Hirsch 1972; Rhineland 1974).

which the medullary cavity was filled with Palacos after reaming and suction The operative technique initially used differed from that described in section 3.4 as used in the ultimate experiment no vent hole was drilled near the lateral femoral condyle and the tubing of the syringe was not filled with cement to its very end.

In the first 7 animals operated on perioperative and immediate post operative mortality was high One animal had to be sacrificed because of a femoral shaft fracture which had occurred during reaming of the medullary cavity During or shortly after introduction of the cement three animals showed pale sclerae and dilatation and downward displacement of the pupil as well as an irregular heartbeat Ventilation with pure oxygen and external heart massage brought no improvement Spontaneous respiration was not resumed There appeared to be a respiratory stand still the irregular heartbeat continuing for a few more minutes

During postmortem examination of the first animal to die in this manner no macroscopical changes were seen However when the right ventricle was opened under water there emerged air bubbles That air embolism had occurred was not surprising because an air column of about 7 cm length was introduced under pressure into the vascular bed which had already been damaged as a result of the reaming This expe

Fig 9 Operative technique Explanation in text pages 56 57

was not allowed to become too deep The operation was completed as outlined sub a)

All operations were performed by the author, assisted by a biotechnician who gave the anaesthetic and an intern in orthopaedics The operation was simple and readily reproducible In all cases without exception the leg thus treated was capable of normal weight bearing after the operation this could be checked because the animals had to stand erect on their hindlegs in order to reach their drinking bottle There were no infections in the area of the operation, and no wound dehiscence occurred

### 3 5 Preliminary experience and explanation of the operative technique used in the ultimate experiment

#### 3 5 1 Introduction

In order to gain an impression of the problems which might pose themselves during the experiment a test group of 25 rabbits was used in

by a few tenths of an atmosphere during insertion of the suction tube and during suction. A marked increase in intramedullary pressure occurred while the cement was being introduced. It was found that the pressure could be regulated by adjusting the rate of introduction of the cement. The mean rise in pressure in the 12 animals was up to 1.4 atmospheres. During rapid introduction of cement the pressure could rise to 2.5 atmospheres (end of the manometer scale). The increase in pressure sometimes persisted for some considerable time once the medullary cavity was completely filled (partly because the apertures in the screw were as a rule also filled with acrylic cement).

In each of the 12 animals the ECG showed accelerated sinus rhythm and lowering of the ST complex, indicative of coronary insufficiency. No straightforward correlation was established between the level of intramedullary pressure measured and the severity of the ECG changes. The 6 animals in which the system leaked showed no ECG changes. Three animals in which the pressure rose to 1.8, 2.3 and 2.5 atmospheres, respectively, succumbed as a result of histologically verified pulmonary fat and bone marrow embolism. In these animals the ECG features were those of a changed electrical heart axis, increasing atrioventricular block with nodal extrasystoles, repolarization disorders and intraventricular conduction disorders (broadened QRS complex).

### 3.5.3 Discussion

The method used to measure intramedullary pressure had some unmistakable disadvantages: a manometer is not a precision instrument, registration is not possible, the occlusion ensured by the screw in the bone was often insufficient (with as a result a pressure measured too low) and the apertures in the screw filled with bone marrow remnants and sometimes with acrylic cement. These measurements were exclusively carried out to gain an impression of the rise in intramedullary pressure and of the extent to which it could be regulated by quicker or slower tightening of the screw spindle of the cement syringe.

Even though these results, which closely resemble those reported by Marsman et al (1975), warrant no absolute or generally valid conclusions, yet they helped in setting up the ultimate experiment. After reaming of the medullary cavity a venthole was drilled immediately proximal to the lateral femoral condyle in all animals used in the ultimate experiment. This was done in order to:

- 1 prevent an excessive rise in intramedullary pressure
- 2 prevent massive pulmonary embolism
- 3 ensure more complete removal of medullary contents

nience taught us therefore to fill the entire length of Teflon tubing with cement before introducing the cement syringe

Of the other two animals, one developed irreversible shock shortly after insertion of the Teflon suction tube, and the other died shortly after introduction of the cement. The deaths of these two animals (with macroscopically normal parenchymal organs at postmortem), however, could not be explained by an air embolism. In these animals massive fat and bone marrow embolisms were found in the lungs when frozen sections were stained with Sudan 4 (fig. 10).

These complications did not occur when a lateral vent hole was drilled in the distal segment of the femur, whereupon the cement was slowly introduced. In view of studies by Danckwardt Lilliestrom (1969) and Danckwardt-Lilliestrom et al. (1970a, 1970b), it seems plausible that the cause of these fat embolisms had to be an increased intramedullary pressure during the operation. In order to estimate the maximum possible increase in intramedullary pressure during the operation, this pressure was measured via a simple system in the next 18 animals. It was also decided to monitor the ECG routinely.

### 3.5.2 Determination of intramedullary pressure with simultaneous electrocardiographic registration

#### 3.5.2.1 Method

A burr hole was drilled immediately proximal to the lateral femoral condyle, a screw thread was tapped and a modified hollow cortex screw (ASIF)\* with a length of 20 mm was inserted and tightened as far as the opposite cortical layer. Two apertures were made at the end of this screw. Via a water filled cannula, the screw was connected with a likewise water-filled standardized manometer. The increase in intramedullary pressure was measured during insertion of the suction tube, suction of the medullary cavity, introduction of the cement and setting of the cement.

Throughout the operation, standard leads I, 2 and 3 on 4 legs were used to register the heart action with the aid of a Mingograf 81 electrocardiograph (Elema Schonander Stockholm Sweden). Arterial blood pressure, central venous pressure, cardiac output and blood gas values were not registered.

#### 3.5.2.2 Results

In 6 of the 18 animals the screw proved to occlude inadequately and no pressure was measured. In the remaining 12 rabbits the pressure rose

---

\* Association for the Study of Internal Fixation Davos, Switzerland

by a few tenths of an atmosphere during insertion of the suction tube and during suction. A marked increase in intramedullary pressure occurred while the cement was being introduced. It was found that the pressure could be regulated by adjusting the rate of introduction of the cement. The mean rise in pressure in the 12 animals was up to 1.4 atmospheres. During rapid introduction of cement the pressure could rise to 2.5 atmospheres (end of the manometer scale). The increase in pressure sometimes persisted for some considerable time once the medullary cavity was completely filled (partly because the apertures in the screw were as a rule also filled with acrylic cement).

In each of the 12 animals the ECG showed accelerated sinus rhythm and lowering of the ST complex, indicative of coronary insufficiency. No straightforward correlation was established between the level of intramedullary pressure measured and the severity of the ECG changes. The 5 animals in which the system leaked showed no ECG changes. Three animals in which the pressure rose to 1.8, 2.3 and 2.5 atmospheres respectively succumbed as a result of histologically verified pulmonary fat and bone marrow embolism. In these animals the ECG features were those of a changed electrical heart axis, increasing atrioventricular block, with nodal extrasystoles, repolarization disorders and intraventricular conduction disorders (broadened QRS complex).

### 3.5.1 Discussion

The method used to measure intramedullary pressure had some unmistakable disadvantages: a manometer is not a precision instrument, registration is not possible, the occlusion ensured by the screw in the bone was often insufficient (with as a result a pressure measured too low) and the apertures in the screw filled with bone marrow remnants and sometimes with acrylic cement. These measurements were exclusively carried out to gain an impression of the rise in intramedullary pressure and of the extent to which it could be regulated by quicker or slower tightening of the screw spindle of the cement syringe.

Even though these results, which closely resemble those reported by Marsman et al. (1975), warrant no absolute or generally valid conclusions, yet they helped in setting up the ultimate experiment. After reaming of the medullary cavity, a venthole was drilled immediately proximal to the lateral femoral condyle in all animals used in the ultimate experiment. This was done in order to

- 1 prevent an excessive rise in intramedullary pressure
- 2 prevent massive pulmonary embolism
- 3 ensure more complete removal of medullary contents

- 4 minimize the risk of intracortical bone marrow embolism which, through obliteration of vascular canals, can greatly contribute to cortical necrosis (Danckwardt Lilliestrom et al 1970b)

In the elegant experiment which Kallos et al (1974) published after completion of this study, the direct correlation between high intramedullary pressure and pulmonary fat embolism was incontrovertibly demonstrated

During digital introduction of acrylic cement and a stainless steel rod in the cement mass into dog femurs they measured intramedullary pressures of 290 900 mm Hg with the aid of a tracer ( $^{99m}\text{Tc}$  macroaggregated albumin) injected into the medullary cavity they established that medullary contents appeared in the lungs within 10 120 seconds When a vent hole was made in the femur the intramedullary pressure did not rise beyond 1 93 mm Hg and no increase in radioactivity was observed in the lungs Histological examination revealed fairly large fat globules in the lungs of dogs with non vented femurs whereas only a few small globules were observed in the lungs of dogs whose femurs had been vented previously

### 3 5 4 Conclusion

In view of preliminary experience gained with 25 rabbits used as a test group we opted for drilling a vent hole in the lateral distal femur in all animals used in the ultimate experiment

### 3 6 Division into groups

The animals were classified according to type of operation and type of acrylic cement used (table 1) The seven groups included 18 animals each (table 2) Intercurrently deceased or disqualified animals (section 3 13) were replaced As described in section 3 4 the operation was always performed on the left femur, the right femur serving as control An exception was made for groups 1 and 3a, which represent bilateral

- 4 minimize the risk of intracortical bone marrow embolism which, through obliteration of vascular canals, can greatly contribute to cortical necrosis (Danckwardt Liljestrom et al 1970b)

In the elegant experiment which Kallos et al (1974) published after completion of this study, the direct correlation between high intramedullary pressure and pulmonary fat embolism was incontrovertably demonstrated

During digital introduction of acrylic cement and a stainless steel rod in the cement mass into dog femurs they measured intramedullary pressures of 290 900 mm Hg with the aid of a tracer ( $^{99m}\text{Tc}$  macroaggregated albumin) injected into the medullary cavity they established that medullary contents appeared in the lungs within 10 120 seconds. When a vent hole was made in the femur the intramedullary pressure did not rise beyond 1 93 mm Hg and no increase in radioactivity was observed in the lungs. Histological examination revealed fairly large fat globules in the lungs of dogs with non vented femurs whereas only a few small globules were observed in the lungs of dogs whose femurs had been vented previously.

### 3 5 4 Conclusion

In view of preliminary experience gained with 25 rabbits used as a test group, we opted for drilling a vent hole in the lateral distal femur in all animals used in the ultimate experiment.

### 3 6 Division into groups

The animals were classified according to type of operation and type of acrylic cement used (table 1). The seven groups included 18 animals each (table 2). Intercurrently deceased or disqualified animals (section 3 13) were replaced. As described in section 3 4, the operation was always performed on the left femur, the right femur serving as control. An exception was made for groups 1 and 3a, which represent bilateral

Table 1 Grouping according to type of operation

Group	Type of operation
1	Reaming and suction of medullary cavity (RS)
2	RS + Palacos rod
3a	RS + commercial acrylic cement (Palacos)
3b	RS + commercial acrylic cement (Sulfix 6)
4a	RS + acrylic cement (Palacos) without catalyst
4b	RS + acrylic cement (Sulfix 6) without catalyst
5	RS + modified acrylic cement Sulfix 6 with CMC gel

after operation and once a week thereafter. The purpose was to evaluate whether the method of cementing was sufficient (i.e. whether the entire femur was filled with cement) and to establish whether fractures had occurred during the operation or became manifest after the operation. In addition it was expected that the femurs treated by operation would increase in circumference as has been the case in the studies of Slooff (1970-1971) who introduced acrylic cement into the medullary cavity in dogs. The radiological follow-up was made to establish whether the same could be observed in rabbit femurs.

### 3.8.1.1 Method

The animal was kept still by intramuscular injection of 0.5 ml/kg Hypnorm (Philips Duphar) and 0.5 mg atropine. It was tied to a specially designed stand and submitted to AP radiography. The roentgen apparatus used was a Philips Super Practix and the film a Kodurex Autoprocess (no screen).

### 3.8.1.2 Results

The medullary cavities of all femurs except two were entirely filled with acrylic cement. In one animal an avulsion fracture of the femoral diaphysis was observed which had been overlooked at operation. The mean increase in femoral circumference was small. A thin low-contrast layer of periosteal bone apposition was usually visible along the entire cortex from the second postoperative week on. The layer attained its maximum thickness after 3 weeks and in the 14 animals with completely cement-filled medullary cavities, caused a mean increase in circumference of 9 per cent, as measured on a fixed point at the centre of the diaphysis. Subsequently the density of this new bone increased, and no further radiological changes occurred after 7 weeks.

### 3.8.1.3 Discussion

The enormous bone apposition which Slooff (1970-1971) observed in cemented dog femurs was not found in rabbit femurs. Since the above described radiographic method was rather cumbersome since the animals' biorhythm was being disturbed every week and since the information obtained was of little value, these radiographs were not included in the ultimate experiment.

### 3.8.1.4 Conclusion

As weekly radiographic follow-up failed to yield anything of value it was abandoned for the animals in the ultimate experiment. Immediately after operation a radiograph was always obtained to make sure that the entire medullary cavity was filled with cement and to ascertain that no fracture had occurred.

operations on the left femur formed group 3a, and operations on the right femur formed group 1. The animals were paired off for sacrifice 1, 2, 3, 4, 5, 6, 7 weeks and 3 and 6 months after operation. This means that for every survival period 2 animals per group were available for examination. Finally, 6 animals were kept alive until 9, 12 and 24 months after the operation (table 2). They were the 6 animals of the test group in which determination of intramedullary pressure had shown no rise due to leakage along the screw. It could therefore be assumed that no significant rise in intramedullary pressure had occurred. The acrylic cement used in these cases was Palacos (section 3.5.2).

### 3.7 *Sacrificing technique*

After intravenous injection of 50 mg (5000 IU) heparin, the animals were sacrificed by intravenous injection of an overdose of pentobarbital sodium (Nembutal). Immediately after cardiac arrest the abdominal cavity was opened and the aorta was cannulated at the level of the renal arteries with a plastic cannula inserted almost as far as the bifurcation. The aorta was ligated proximal to the site of cannulation. The inferior vena cava was opened. From a constant height of 100 cm (the most common physiological perfusion pressure) irrigation was effected with 1 litre physiological saline. The cannula was then connected with an infusion flask filled with a Micropaque® suspension\*. This was a 6 per cent barium sulphate solution made from Micropaque 70 per cent W/W fine granular barium sulphate and 35 g sodium citrate in 1 litre physiological saline. The first 300 ml of this solution could be run in quickly, the rest followed at a steady drip. As a rule, the suspension freely escaped from the inferior vena cava after about 1 minute. It took about 90 minutes for perfusion of the total amount of 1000 ml Micropaque suspension to be completed. The perfusion pressure was not measured. Next both femurs were ex-articulated in hip joint and knee joint leaving an ample muscular cover in order to leave the periosteum intact. The bones were immediately numbered, packed in plastic bags and deep frozen to  $-18^{\circ}\text{C}$ .

### 3.8 *Radiological technique*

#### 3.8.1 Radiographs during the period of observation

In the animals of the test group, radiographs of the pelvis and both femurs were made by a standard method before operation immediately

\* Micropaque® (Microtrast) Oesophageal Cream is supplied by Dainancie & Co Ltd Slough (Bucks) Great Britain

Fig 11 Schematic representation of segments used for decalcified and non decalcified sections

Decalcified sections thus obtained were embedded as a histological section with a non fluorescent adhesive (DPX) and studied with the fluorescence microscope (section 3 11) The procedure described caused disappearance of acrylic cement from the bone by dissolution in trichloroacetic acid toluene chloroform xylol and acetone

### 3 10 Microangiography

To obtain microangiograms of the non-decalcified sections from segments A B C and D of left and right femur use was made of a micro-radiogram arrangement with a Philips self rectifying X ray generator type IW 1008 and Kodak spectroscopic safety film type 649-0 (20 min 20 kV 30 mA) The sections were placed directly on the film the distance from the tube being 20 cm The microradiograms obtained were placed on a slide and examined with the light microscope

### 3 8 2 Postmortem radiographs

To assess the degree of filling of vessels with Micropaque, radiographs were made in two directions of all deep frozen femurs, using mammography equipment with a molybdenum anode. Very fine grained industrial roentgen film was used so that enlargements were possible if required. This technique has been found very suitable for evaluation of bone structure (Meema et al 1972, Hendriks 1975).

### 3 9 Histological technique

Of the deep frozen femurs with soft tissue lining only the diaphysis and a small part of the lower metaphysis were used. This was manually cut into 7 transverse segments of about 0.75 cm thickness, which were numbered A, B, C and D from proximal to distal end. Segment C was bisected longitudinally, thus giving a total of 8 bone fragments. Of each segment A, B, C and D, one half was decalcified for paraffin processing and the other half was not decalcified but destined for embedding in plastic. The segments A, B and D were cut into transverse and segment C into longitudinal sections (fig 11). The procedure to obtain paraffin sections was decalcification during 2 days in 5 per cent trichloroacetic acid (which is also a fixative fluid which ensures persistent stainability) followed by washing with 90 per cent alcohol for 1 hour and then dehydration with 70 per cent alcohol, 80 per cent alcohol and 90 per cent alcohol and toluene (each during 24 hours), finally followed by degreasing with chloroform during 12 hours. Next, the tissue fragments were soaked in paraffin during 12 hours in an incubator at 60° C to ensure evaporation of the chloroform. The fragments were then embedded in paraffin and a Leitz microtome was used to cut 5 micra sections. These sections were stained with haematoxylin eosin and according to Goldner (Romeis 1968, Schenk et al 1969). The Goldner stain gives non mineralized connective tissue (e.g. osteoid) an orange red colour, bone stains green, cells black, cytoplasm orange and muscular tissue reddish violet.

The procedure to obtain the non decalcified sections was fixation in 70 per cent alcohol during about 16 hours followed by dehydration with 80 per cent alcohol, 96 per cent alcohol, 100 per cent alcohol, acetone and toluene (each during 24 hours). The slices were then embedded in methyl methacrylate and after curing cut into 110 micra sections with a diamond section cutting machine (instrument workshop, Department of Dentistry, University of Groningen). These sections were polished on both sides (Kent MK<sub>2</sub> polishing machine, Engis, Alphen a/d Rijn, Netherlands) until a thickness of 100 micra was attained. They were not stained. The non

decalcified sections thus obtained were embedded as a histological section with a non fluorescent adhesive (DPX) and studied with the fluorescence microscope (section 3.11). The procedure described caused disappearance of acrylic cement from the bone by dissolution in trichloroacetic acid, toluene, chloroform, xylol and acetone.

### 3.10 Microangiography

To obtain microangiograms of the non decalcified sections from segments A, B, C and D of left and right femur, use was made of a micro-radiogram arrangement with a Philips self rectifying X ray generator type PW 100b and Kodak spectroscopic safety film type 649-D (20 min 20 kV 30 mA). The sections were placed directly on the film, the distance from the tube being 20 cm. The microradiograms obtained were placed on a slide and examined with the light microscope.

### 3 8 2 Postmortem radiographs

To assess the degree of filling of vessels with Micropaque, radiographs were made in two directions of all deep frozen femurs, using manumography equipment with a molybdenum anode. Very fine grained industrial roentgen film was used so that enlargements were possible if required. This technique has been found very suitable for evaluation of bone structure (Meema et al 1972, Hendriks 1975).

### 3 9 Histological technique

Of the deep frozen femurs with soft tissue lining, only the diaphysis and a small part of the lower metaphysis were used. This was manually cut into 7 transverse segments of about 0.75 cm thickness, which were numbered A, B, C and D from proximal to distal end. Segment C was bisected longitudinally, thus giving a total of 8 bone fragments. Of each segment A, B, C and D, one half was decalcified for paraffin processing and the other half was not decalcified but destined for embedding in plastic. The segments A, B and D were cut into transverse, and segment C into longitudinal sections (fig 11). The procedure to obtain paraffin sections was decalcification during 2 days in 5 per cent trichloroacetic acid (which is also a fixative fluid which ensures persistent stainability), followed by washing with 90 per cent alcohol for 1 hour and then dehydration with 70 per cent alcohol, 80 per cent alcohol and 90 per cent alcohol and toluene (each during 24 hours), finally followed by degreasing with chloroform during 12 hours. Next, the tissue fragments were soaked in paraffin during 12 hours in an incubator at 60° C to ensure evaporation of the chloroform. The fragments were then embedded in paraffin and a Lenz microtome was used to cut 5 micra sections. These sections were stained with haematoxylin eosin and according to Goldner (Romeis 1968, Schenk et al 1969). The Goldner stain gives non mineralized connective tissue (e.g. osteoid) an orange red colour, bone stains green, cells black, cytoplasm orange and muscular tissue reddish violet.

The procedure to obtain the non decalcified sections was fixation in 70 per cent alcohol during about 16 hours, followed by dehydration with 80 per cent alcohol, 96 per cent alcohol, 100 per cent alcohol, acetone and toluene (each during 24 hours). The slices were then embedded in methyl methacrylate and, after curing, cut into 110 micra sections with a diamond section cutting machine (instrument workshop Department of Dentistry University of Groningen). These sections were polished on both sides (Kent MK<sub>2</sub> polishing machine, Engis Alphen a/d Rijn, Netherlands) until a thickness of 100 micra was attained. They were not stained. The non

mycin® Pfizer) 24 hours before sacrifice they were given 50 mg Alizarin Red S as 1 per cent sterile solution likewise by intravenous injection

For the animals used for macro-autoradiography, no exception was made to this rule in view of the possibility that Terramycin in the dose given could have a slight inhibitory effect of bone formation (Danckwardt Lilliestrom 1969 Rahn 1973) The two animals which survived 7 weeks after operation in each of the groups 1 through 5 were in addition given weekly one of the above mentioned newer fluorochromes as 3 per cent sterile solution (Rahn and Perren 1970 1971 1972) according to the plan shown in table 3

To study and photograph the sections we used a modified Zeiss Universal microscope with fluorescence equipment the vertical illuminator III RS and the attached camera LS Matic (Verhofstad and Schnyer 1975) Incident light excitation was used In relation to the light direction the sequence of the optical system used was as follows

Light source	high pressure mercury vapour lamp OSRAM HBO 200 W/4 heat absorption filter KG 1 red absorption filter BG 38
III RS (position 3) with (blue light excitation)	excitation interference blue filter KP 500 excitation interference blue filter KP 490 dichroitic interference mirror FT 510 barrier filter LP 520
or III RS (position 1) with (UV excitation)	UV permeable black glass UG 1 dichroitic interference mirror FT 420 UV barrier filter LP 418
Objective	Neofluar 63 02

For the colour reproductions presented in chapter 4 only position 3 of the vertical illuminator III RS was used the calcein blue which fluoresced only in position 1 is therefore not visible in these reproductions (table 3) The colour as reproduced on the film used (daylight film Kodak HS 23 DIN Eltachrom EH 135) visually corresponded with the colour of the microscope image Exposure times were 2 20 seconds.

### 3 12 Macro-autoradiography

Autoradiography shows the distribution of radioisotope labelled compounds over the various tissues Bone seeking radioisotopes are deposited in new and incompletely mineralized osteons and make it possible qualitatively to demonstrate distribution patterns in bone and such processes as growth and repair In combination with histological and fluorescence techniques it can be used to differentiate between processes of bone degeneration and bone regeneration

To put it simply the image produced by the radioactivity from a sample on a photographic emulsion is an autoradiogram On the developed film the sites where the radioactive element is localized appear as dark areas The Strontium ion used in this study so closely resembles

### 3 11 Fluorochrome labelling

Ordinary histological sections do no justice to the dynamics of such processes as growth, remodelling and regeneration of bone. The use of vital staining agents which are bound to newly formed bone of any origin (Harris 1960, Harris et al 1964, Frost 1969) has added a new dimension to the study of these dynamic processes.

In addition to the best-known fluorochromes, the tetracyclines (Milch et al 1958, Harris 1960, Harris et al 1962), a need has arisen for other vital staining agents to be used in sequential labelling (Olerud and Lorenzi 1970, Rahn 1973). Alizarin Red S is perhaps too toxic (Harris 1960, Adkins 1965). Moreover, it has been reported to inhibit bone formation (Harris et al 1964), although others have refuted this (Vilman 1969). Olerud and Lorenzi (1970) used it only immediately before sacrificing the test animal.

Fluorochromes for experimental use which have a low systemic toxicity and no local effect on calcification, and at the same time give clearly defined colour differences are calcein (Suzuki and Mathews 1966), calcein blue (Rahn and Perren 1970), xylenol orange (Rahn and Perren 1971) and Alizarin complexon (Rahn and Perren 1972).

During induction of anaesthesia all the animals used in the experiment received an intravenous injection of 50 mg/kg oxytetracycline (Terra

*Table 3* Fluorochromes given for sequential labelling to the animals observed over a period of 7 weeks

Fluorochrome	Dose per kg body weight	Mode of administration	Time of administration in weeks	Vertical illuminator III RS colour in

	(total)		( 24 hrs)		

### 3.13 Disqualified animals

A total of 19 animals (13.5 per cent) were disqualified from the ultimate experiment in which 141 animals were used. Of these 19 animals 8 showed a femoral shaft fracture which in 7 instances was noticed only on postmortem radiographs or at examination of the histological sections. In 3 animals the femurs proved to be insufficiently filled with acrylic cement. Four animals, all from group 4 (acrylic cement without catalyst) died during operation from histologically demonstrated fat embolism. Two animals died shortly after intravenous injection of Alizarin Red S and two died from an intercurrent disease.

### 3.14 Summary

In 7 x 18 rabbits femurs the medullary cavity was reamed, a vent hole was drilled and the medullary contents were removed by suction. In view of preliminary experience with a test group of 25 animals the vent hole was drilled as routine procedure.

The procedure was continued by filling the medullary cavity with acrylic cement. Dependent on the type of acrylic cement used the animals were divided into 7 groups:

- ~ only reaming and suction (group 1)
- ~ insertion of a loose fitting intramedullary Palacos rod (group 2)
- ~ filling of the medullary cavity with commercial acrylic cement (groups 3a and 3b)
- ~ filling with acrylic cement without catalyst (groups 4a and 4b)
- ~ filling with a modified acrylic cement Sulfix-6 with CMC gel (group 5)

The animals were sacrificed in pairs 1, 2, 3, 4, 5, 6 and 7 weeks and 3 and 6 months after operation and the lower limbs were perfused with a Micropaque suspension. The femurs were processed for radiological, histological, microangiographic and fluorescence microscopic examination. The acrylic cement dissolved during processing of microscopic sections. Six animals in which commercial acrylic cement had been implanted were followed up over periods of 9, 12 and 24 months. Of 10 animals from each group (1, 2, 3a, 4a and 5) the femurs were used for macro-autoradiography after 1 or 4 weeks. In 2 animals from each of the two groups 4a and 5 an autoradiogram was made after 4 months.

the calcium ion that it is incorporated in bone crystals in an identical way.  $\text{Sr}^{89}$  is a beta emitter with a half life of 51 days (McLean and Budy 1964).

The femurs of 10 rabbits (2 from each of the 5 principal groups) were micro autoradiographically studied 1 and 4 weeks after operation. In 2 rabbits from groups 4a and 5, an autoradiogram was made after 4 months (table 4).

The survival of rabbits after injection of  $80 \mu\text{Ci } ^{89}\text{Sr} - \text{SrCl}$  in aqueous solution (Amersham) was always 24 hours. Immediately after sacrificing the animals both femurs were removed and immersed for 10 minutes in a chilling mixture of dry ice and isopentane ( $-65^\circ \text{C}$  to  $-75^\circ \text{C}$ ). Until further processing the bones were stored in a freezer at  $-18^\circ \text{C}$ . The bones were fixed by embedding them in a suspension of carboxymethylcellulose in water (5 per cent, medium viscosity, temperature  $0^\circ \text{C}$ ). After embedding the bones the CMC suspension was frozen by chilling it to  $-15^\circ \text{C}$ . The CMC bloc was mounted on the movable stage of a microtome (Jung K) placed in a freezer ( $-15^\circ \text{C}$ ). Sections of 30 micra thickness were fixed on tape (Scotch 810 3AW) during cutting. The strips of tape were then stretched on cardboard sheets. Before a film (Agfa Gevaert Structurix D7) was placed on the fixed sections it was dried in a freezer ( $-18^\circ \text{C}$ ) during 48 hours. The exposure time of the film was about 5 days.

*Table 4* The animals used for  $\text{Sr}^{89}$  macro autoradiography, classified according to type of operation and period of observation

Rabbit no	Group	Type of operation	Survival in weeks
6463	1	RS*	1
6464	1	RS	4
6559	2	RS + Palacos rod	1

- ✓ group 1 reaming (R) and suction (S)
- group 2 RS + Palacos Rod
- ✓ group 3 RS + PMMA
- group 4 RS + PMMA without catalyst
- group 5 RS + modified Sulfix 6 with CMC gel

## 4.2 Macroscopic findings

Apart from a slightly larger diameter as compared with the control bone, the deep-frozen femurs showed no relevant changes. Near the lateral femoral condyle at the site of the vent hole, some callus tissue was usually found. The distal cut surface was chosen in such a way that this callus tissue did not fall in the most distal sector (D). Once the femurs were cut into sections it was invariably found that the acrylic cement always filled the entire medullary cavity and was always fixed firmly to the bone, regardless of the type of cement used. This did not apply to the loose fitting rods in group 2; these however were encapsulated by regenerated bone marrow.

## 4.3 The normal histological features of the other femur used as control

The normal histological features of the transverse section of the control femur show throughout the specimen osteons with vital osteocytes

## CHAPTER 4

### RESULTS

#### 4.1 Premises

The typical reactions which occur in medullary cavity, cortex and periosteum following an intramedullary intervention have been described in detail in chapter 2. The same reproducible histological changes were observed also in our material, and need not be discussed in detail again in this chapter.

In this discussion of results emphasis will be placed on a *comparison* of the changes observed in the various groups. In all cases sections of the treated femur were also compared with those of the control femur. Since no measurements were made the observations are only graphic and descriptive, and not suitable for statistical analysis.

The histological sections provided the basis for the material studied. All other investigations were complementary and helped to confirm the observations made on the histological material. To avoid repetition the entire histological material including the fluorescence microscopic findings will be collectively discussed in sections 4.3 and 4.4. An exception will be made for the animals studied by sequential fluorochrome labelling during 7 weeks (sections 4.6 and 4.7).

In the Goldner stained sections the distribution and intensity of stained osteoid varied from section to section. Sometimes the osteoid was stained in one animal but not in the other. On the whole the data obtained provided too little constant information to warrant definite conclusions. A detailed discussion would be detrimental to the surveyability of this documentation.

It was also found that longitudinal sections C (fig. 11) supplied no new information shortly after the start of the ultimate experiment therefore section C was used for making transverse sections.

Since no essential differences in the reaction pattern of cortex, medullary cavity and periosteum were observed in the material from groups 3A (commercial acrylic cement Palacos) and 3B (commercial acrylic cement Sulfix 6), the two groups will be discussed under the joint heading group 3 RS + PMMA. The same applies to groups 4A and 4B which

Fig 6 Separation of the fragments in various types of patellar fracture

Fig 7 Function of the quadriceps apparatus with respect to separation of the fragments in 416 patients with 4 patellar fractures

Of the patients who were considered to suffer from loss of active function of the quadriceps apparatus 109 (79%) had a separation between the fracture parts of at least 4 mm (Fig 7). The diastasis did not exceed 5 mm in any of the 16 patients who had impaired active extension of the knee.

A step in the articular surface of the patella of 3 mm or more in concomitant diastasis less than 4 mm was found in six patients (Fig 8). Five of these had preserved active extension of the knee while one had loss of active extension.

than 10 mm and as considerable if the separation between the fragments was at least 10 mm. There was no dislocation in 216 fractures (51%) Fig 4. In a further 10 per cent the diastasis was less than 4 mm. In 125 fractures (30%) the diastasis was 4 mm or more. Of these 86 fractures (20%) had a diastasis of at least 10 mm.

Considerable diastasis was observed in 35 per cent of the fractures caused by fall from height (Fig 5). The diastasis was often slight in falling in the same plane.

Transverse fractures with a split lower pole were often dislocated. In 61 per cent there was a separation between the fragments of at least 10 mm (Fig 6). Considerable diastasis was established also in transverse fractures with two large fragments (29%) and in comminuted fractures (22%). Only in exceptional cases was there a considerable diastasis in transverse fractures with a split upper pole as well as in apical and basal fractures. In longitudinal fractures the diastasis did not in any case exceed 4 mm.

Fig 5 Distribution of 422 patellar fractures with regard to various modes of injury and resulting separation of the fragments

(68%) and operative treatment on 135 fractures in 134 patients (32%). The distribution of non surgical and surgical treatment with regard to various age groups among males and females is tabulated in Fig 9

The methods used in non surgical treatment are mentioned in Table 11

Non surgical treatment as a rule included immobilization in plaster reaching from the malleoli to the inguen. In some cases the haematoma in the knee was first punctured. An elastic adhesive bandage was regarded as adequate in some cases while in others no treatment was considered necessary

Of the 282 non surgically treated patients 214 were ambulant and 68 were treated as inpatients. The median period of hospitalization was six days

Fig 1 Relation between diastasis and articular surface step in 422 patellar fractures

### Treatment

On the same day of the trauma 306 patients (74%) came for treatment to the hospital and 83 (20%) within a week. The remaining 27 (6%) did not come to the hospital until one week or more had elapsed. 202 (48%) were treated as in patients.

The treatment was given at El mansha sjukhuset (1/1-15/10 1959) at the two Clinics of Orthopaedic Surgery and at the Surgical Clinics.

The treatment was selected according to the following principles. Non-operative methods were considered applicable if the difference in level between the fragments was less than 3 mm if the patient could lift his leg with his knee extended and/or if the diastasis between the fracture parts was less than 4 mm. If there was loss of active extension despite the diastasis being less than 4 mm the patients were hospitalized. If the extension capability was restored—possibly after puncture of the joint—the patients were not subjected to surgery. In all the other cases surgery was indicated.

Owing to loss of active extension eleven patients were surgically treated despite the diastasis between the fragments being less than 4 mm. In four cases it was stated that the lateral expansions were uninjured and in two that they were torn. In five cases the statements were unreliable.

Five patients were surgically treated despite there not being any loss of active extension and despite the diastasis between the fragments being less than 4 mm. In these cases the lateral expansions were uninjured.

Six patients were not operated on despite the diastasis between the fracture parts being 4 mm or more. Of these five had impaired active function of extension and one patient had sustained polio and wore a lower extremity support.

Non-operative treatment was performed on 287 fractures in 282 patients.

Fig. 11 See text on page 36

The main principle was to restore the normal anatomy of the patella. The most common method of operation was osteosynthesis with a stainless steel wire inserted through two longitudinally drilled holes. In principle the operation was performed as follows. The operation was made in a bloodless field.

Fig 10 Cumulative distribution graphs showing period of immobilization in plaster cast in various non operatively treated types of patellar fracture (L=longitudinal fractures C=comminuted fractures T=all types of transverse fractures )

Table 12 Surgical methods of treatment for various types of patellar fracture Other methods for osteosynthesis were metal pin (one case) metal wire through cross drill d holes (two cases) suture with silk linen or catgut (five cases)

Treatment										Total
Osteosynthesis										
longitudinally drilled holes	21	3	30	13						67
transversally drilled holes			1					1		4
encircling wire	5	1	3	3						12
other methods	1	1	2		3		1			8
Partial patellectomy		2	21	3		2	5	1		34
Total patellectomy	1			5						6
Exploration	1							1		2
Total	31/66	7/13	57/74	24/60	3/92	2/25	8/10	3/23	13/47	

The approximate median period of immobilization in plaster after non surgical treatment was four weeks and shorter for longitudinal fractures than for transverse and comminuted (Fig 10)

When there was an indication for surgery the operation was performed on the same day or on that following The methods of operation employed are given in Table 12

Fig 11 see text on page 37

The main principle was to restore the normal anatomy of the patella. The most common method of operation was osteosynthesis with a stainless steel wire inserted through two longitudinally drilled holes. In principle the operation was performed as follows. The operation was made in a bloodless field.

E

F

Fig 11 Transverse fracture of the patella with two large fragments (A) treated by osteosynthesis with metal wire through longitudinally drilled holes (B-C) B shows two Kirschner wires piercing the fragments (The result eight years later (D-F) was excellent)

After making a medial parapatellar incision the prepatellar bursa was extirpated. The joint cavity was syringed carefully with physiological saline solution. The tear of the lateral expansions was identified. After removing any small fragments the fracture parts were fastened together by means of bone clamps. Two Kirschner wires with a needle eye were drilled parallelly into the proximal fragment starting at the basis (Fig 11). As it was often impossible to drill through both fragments at the same time the wires were drilled across the line of the fracture far enough to allow distinct impressions to be made in the distal fragment. This indicated where another pair of Kirschner wires could be inserted. A 0.9 mm stainless steel wire was attached to the Kirschner wires and drawn back to the basis where it was tightened with a wire twister. Then the wire ends were recessed into a channel made with an awl in the basis of the patella. Restoration of the articular surface was very much facilitated by inserting a finger into the joint and at the same time hyperextending the knee thus permitting the articular surface to be palpated (Moberg 1944). After completing the osteosynthesis the tear of the lateral expansions was repaired with catgut or silk.

Partial patellectomy retaining one large fragment was the most important alternative to osteosynthesis and was mainly used in transverse fracture with a split lower pole (Fig 12)

A

B

C

Fig 1 Transverse fracture of the patella with a split lower pole (A) treated by partial patellectomy (B) (The result ten years later (C) was excellent)

Fig 13 Cumulative distribution graphs showing duration of immobilization in plaster cast in patellar fractures treated by osteosynthesis and partial patellectomy (P=partial patellectomy O=osteosynthesis)

Only in exceptional cases—in open fractures—was the patella completely excised

In open injuries the fracture was surgically treated in 19 out of 23 cases. The operation was performed at the acute stage with one exception. In nine cases osteosynthesis was carried out in five the patella was partly excised and in another five total patellectomy was performed.

After the operation the leg was immobilized in a plaster cast reaching from the malleoli to the inguen and the knee was fixed in a flexed position of 5–10 degrees. As a rule there was no drainage. Generally the patient remained in bed for 3–4 days after the operation with the leg elevated. Isometric exercise of the quadriceps muscle was begun on the day after the operation. After a few days leg raising exercises were instituted. Crutches were used after the mobilization as protecting support but weight bearing was allowed.

The median period of hospitalization in operative treatment was twelve days.

The median period of immobilization in plaster cast was 6.5 weeks (Fig 13). This period did not vary with the methods of operation.

When the plaster cast had been removed the patient was given verbal instructions about extension and flexion exercises. A physiotherapist supervised when necessary.

### Complications

No patient died owing to fracture of the patella. There were complications in 19 patients (5%) Table 13.

Four patients sustained refracture after osteosynthesis. In three of these cases the operation had been performed with a stainless steel wire inserted through longitudinally drilled holes. The group "Other Complications" included five patients. Two of these got paralysis of the peroneus which became permanent in one. Suture migration was found in two patients. Finally in one patient there was a lengthening of the quadriceps tendon after total excision of the patella; on re-operation shortening of the tendon was performed.

In none of the cases severe infection of the joint set in. No cases of deep thrombosis nor thromboembolism were diagnosed.

### Re operations

22 patients (5%) were re-operated on (Table 14).

Release of adhesions was performed in eleven cases. If the mobility was considerably impaired the patella was mobilized during complete relaxation of the muscles. In no case was this manipulation carried out earlier than two months after the trauma. A sharp hook was inserted percutaneously at the basis

Table 13 Complications in 19 out of 416 patients with fracture of the patella

Treatment	Complications			
	Wound infection	Refracture	Other	Total
Non-operative		-	1	3
Osteosynthesis	5	4	1	10

Fig 14

Fig 15

Fig 14 Cumulative distribution graphs showing period of sick leave after closed and open fracture of the patella. Concomitant injuries are included (C=closed fracture O=open fracture)

Fig 15 Cumulative distribution graphs showing period of sick leave in preserved and lost function of the quadriceps in fracture of the patella. Open fractures and concomitant injuries are excluded (P=preserved quadriceps function L=lost quadriceps function)

of the patella lifting the patella slightly. By pressing the thumb against the patella it was carefully worked loose. Small movements from side to side were also brought about. By this careful manipulation it was possible to avoid breaking forces of the fracture line or tension of the row of sutures. The mobilization had in all cases the intended effect and involved no complications.

Four patients were included in the group of Other Re operations; the one mentioned above on whom a shortening of the quadriceps tendon was performed, two in whom sutural granulomas were extirpated and one on whom an explorative arthrotomy was done in a late phase because of diffuse joint pain. In this case there was a slight defect corresponding to the fracture.

### Sick leave

Of 416 patients 306 received sickness benefit. The period of sick leave also depended on factors other than the fracture. There was no difference between the sexes nor between the occupations in the length of time of sick leave. After open fracture the median period of sick leave was twice as long as that after closed (Fig 14). If the extensor function was preserved indicating a minor injury to the lateral expansions, half the number of patients was discharged after two months (Fig 15). If there was loss of active extension, four months elapsed before half the number of patients had recovered.

Fig 16

Fig 17

Fig 16 Cumulative distribution graphs showing period of sick leave for different types of patellar fracture. Open fractures and concomitant injuries are excluded (L=longitudinal lateral fractures C=comminuted fractures T=transverse fractures with two large fragments Tlp=transverse fractures with a split lower pole)

Fig 17 Cumulative distribution graphs showing period of sick leave with different methods of treatment in patellar fractures. Open fractures and concomitant injuries are excluded (Pl=plaster cast—non-operative treatment Pa=partial patellectomy O=osteosynthesis)

Longitudinal lateral fracture (as well as longitudinal medial apical and basal fracture) resulted in shorter periods of sick leave as compared with other types of fracture (Fig 16)

Of the patients with a longitudinal lateral fracture 68 per cent were discharged after two months as restored but of those who had a transverse fracture with two large fragments only 22 per cent

The median period of sick leave for patients with a fracture not requiring surgical treatment was half of that required for patients with a fracture treated surgically (Fig 17)

After four months 91 per cent of the non surgically treated patients immobilized in a plaster cast had returned to work but only 49 per cent of those on which osteosynthesis had been performed. The median period of sick leave was slightly shorter after partial patellectomy than after osteosynthesis

#### Certificate of disablement

After the treatment was terminated 19 patients received a certificate of disablement. Two of these had concomitant injuries. Of the remaining 17 patients five were granted lifelong compensation equivalent to a reduced capacity for work by 10-20 per cent. Temporary compensation was granted to two patients. The reduced capacity for work in the remaining ten cases was not found to exceed 10 per cent.

## CHAPTER IV

### FOLLOW—UP STUDY

#### Case series

The follow up study was carried out during the period 1970–1971. The time of observation varied from 5 to 12 years. The mean time of observation was 8.9 years. The follow up study included 321 subjects (327 fractures) constituting 91 per cent of those alive at the time of the investigation. 63 subjects had died. 32 subjects were impossible to reach for various reasons. Of the 321 subjects 247 were thoroughly examined according to the method mentioned below. A further 25 subjects, most of whom were elderly, were examined in nursing homes, homes for the aged or in their own homes, but were not radiographically examined. The remaining 49 answered questionnaires, but were not examined. Of these 49 subjects 21 were asked to come for examination more than four times but refused. 22 lived more than 50 km from the hospital and a further six had died before the clinical investigation was terminated.

From the time of injury to the time of the follow up 16 subjects sustained diseases and injuries in the same extremity earlier injured. Of these eleven sustained a fracture of the femoral neck, two other kinds of fracture and three injury of the meniscus. Four subjects were struck by diseases and injuries in the other leg. Two of these sustained a fracture of the femoral neck, one a fracture of the ankle joint and one injury of the meniscus. These 20 subjects are included in the series.

One subject later sustained a new fracture of the patella of the same leg and was subjected to total patellectomy. He was excluded from the series. Two subjects later fractured the patella of the other leg. These two latter fractures were not treated surgically. The second fracture caused no discomfort. They are included in the series, but the other knee injured later was regarded as uninjured.

When checking the series it was found that of the six subjects who had sustained bilateral fractures of the patella, four had one slightly and one severely injured knee, the latter of which only had been surgically treated. One subject was non-surgically treated bilaterally and the remaining was operated on both sides. The condition of the latter subject at the follow up

Fig 18 Distribution of age and sex among 320 subjects with fracture of the patella at the follow up study

was affected by the sequelae of a cerebral insult. One knee of the two latter subjects and the slightly injured knee of the other four will in the following be regarded as uninjured. The percentage of the poor results in the final report will not be affected by this exclusion.

In the continued report of subjective symptoms the series includes 320 subjects. The objective and radiographic findings are based on 271 and 246 subjects respectively.

The distribution of the patients followed up with regard to age and sex is indicated in Fig 18.

The mean age of the subjects followed up was 53 years, i.e. for 194 males 47 years and for 136 females 61 years. The youngest subject was 21 years and the oldest 96 years of age.

The distribution of non-operative and operative treatment among various age groups of males and females in the follow up study is stated in Fig 19.

Methods of treatment of various types of fracture are specified in Table 15.

### Methods

A questionnaire was sent to the subjects in which they were asked to state the following symptoms and active function as conceived before and after the injury: pain, swelling, stiffness, untenderness, limping, use of stick, capability for walking, mounting stairs, running and sports. Furthermore they mentioned further sick leave because of the same injury, change of occupation, life annuity and whether they believed that the injury had caused permanent disability.

At the clinical examination between six and twelve months later the questionnaire was verbally discussed. The conclusion of the verbal and written answers was satisfactory and consequently it was believed that the subjects whose condition was assessed merely on the basis of the questionnaire had given an adequate account of their condition.

## CHAPTER IV

### FOLLOW—UP STUDY

#### Case series

The follow up study was carried out during the period 1970–1971. The time of observation varied from 5 to 12 years. The mean time of observation was 8.9 years. The follow up study included 321 subjects (327 fractures) constituting 91 per cent of those alive at the time of the investigation. 63 subjects had died. 32 subjects were impossible to reach for various reasons. Of the 321 subjects, 247 were thoroughly examined according to the method mentioned below. A further 25 subjects, most of whom were elderly, were examined in nursing homes, homes for the aged or in their own homes, but were not radiographically examined. The remaining 49 answered questionnaires, but were not examined. Of these 49 subjects, 21 were asked to come for examination more than four times but refused. 22 lived more than 50 km from the hospital and a further six had died before the clinical investigation was terminated.

From the time of injury to the time of the follow up, 16 subjects sustained diseases and injuries in the same extremity earlier injured. Of these eleven sustained a fracture of the femoral neck, two other kinds of fracture and three injury of the meniscus. Four subjects were struck by diseases and injuries in the other leg. Two of these sustained a fracture of the femoral neck, one a fracture of the ankle joint and one injury of the meniscus. The 20 subjects are included in the series.

One subject later sustained a new fracture of the patella of the same leg and was subjected to total patellectomy. He was excluded from the series. Two subjects later fractured the patella of the other leg. These two latter fractures were not treated surgically. The second fracture caused no discomfort. They are included in the series, but the other knee injured later was regarded as uninjured.

When checking the series it was found that of the six subjects who had sustained bilateral fractures of the patella, four had one slightly and one severely injured knee, the latter of which only had been surgically treated. One subject was non surgically treated bilaterally and the remaining was operated on both sides. The condition of the latter subject at the follow up

The nature and degree of pain and the subjectively experienced impairment of function was assessed on the basis of verbal and/or written questioning. Pain and ache were classified according to the following:

- 1 Temporary ache e.g. with atmospheric changes or in kneeling posture
- 2 Ache when starting to walk or in connection with a lengthy position e.g. in a squatting posture
- 3 Ache in connection with exertions
- 4 Ache caused by all activities
- 5 Pain at rest

In analyzing the impairment of function consideration was taken to the age of the subject. An age limit of 60 years was selected and the functions included were scored (Table 16).

At the clinical examination walking on a level surface as well as the capability of mounting and descending stairs were assessed. Extension defect and range of mobility of the knee joints were measured with an angle gauge. The maximal circumference of the calf, the circumference on a level with the patella and the circumference of the thigh 15 cm proximally to the medial interarticular space were measured on both legs.

Methods of measuring the extension force of the knee have been elaborated by Clarke *et al.* (1950). He suggests a sitting posture with the knee joint

Table 16. Estimation of subjectively experienced impairments of function

Subjectively experienced impairment of function	Age in Years	
	≥ 60	< 60
Feeling of unsteadiness or weakness	1	0
Limping — following exertions	0	1
— always	1	2
Stiff foot — only out doors	1	1
— always	0	2
Walking distance — impaired (< 5 km)	2	2
— severely impaired (< 1 km)	4	4
Walking up and down stairs — slowly but with alternating steps	1	1
— mounting stairs with healthy leg first and descending stairs with the impaired leg first	2	-
Running — impaired	0	2
Stair — impaired	0	0
Maximal score	10	16

Fig. 10 Subjective symptoms after non-operative and operative treatment of fracture of the patella. (The figures refer to percentages and number of subjects.)

## Results

### Subjective Symptoms (370 subjects)

When the treatment ended 78 subjects (21%) did not consider themselves to be fully recovered. At a later date 44 (14%) came for consultation because of discomfort which could depend upon the injury. An operation was performed on eight of these. At the time of the questioning 223 (70%) were satisfied.

The pain in the injured knee was considered as slight if it occurred in connection with kneeling or atmospheric changes, as moderate when starting to walk and as the result of a lengthy squatting posture or during exertions. The pain was regarded as severe if it persisted at rest and/or in all activities. It was found that 157 subjects (49%) had no pain and 63 (20%) had slight pain. Moderate pain was noted in 59 (18%) and severe in 42 (13%) subjects.

The subjectively experienced impairment of function was considered slight if the corresponding score did not exceed 2 points. The impairment of function was moderate if the score exceeded 2 but not 4 and 6 points respectively. If the score was higher the impairment of function was classified as considerable. No abnormality of the function was stated by 202 subjects (63%). Slight impairment of function was found in 51 (16%), moderate in 14 (6%) and considerable in 49 (15%) subjects.

Subjective symptoms after non-surgical and surgical treatment are indicated in Fig. 20.

None of the 49 subjects who merely answered the questionnaires had severe

flexed through 45 degrees Tornvall (1963) and Backlund & Nordgren (1969) measured the force with the subject in a sitting posture and the knee joint flexed through 90 degrees. The mean value of the subjects aged 20-28 years was in the Tornvall series 50 kgf on the right and 47 kgf on the left side. In medical students of the same age Backlund & Nordgren found 65 kgf on the right and 64 kgf on the left side.

The force of the extensor muscles was measured in a special chair designed by Hook & Tornvall (1969) and equipped with a strain gauge dynamometer for measuring isometric power muscles. The knee was flexed through 90 degrees. The maximal force was recorded—often after several attempts, the last value obtained being lower than the highest—and a percentage of the reduction of force was calculated on the force of the uninjured leg. Measurements of the force of the knee extension was made with the assistance of Eva Landegren, laboratory assistant, Dept of Medical Rehabilitation II Sahlgren's hospital. In cases when the subjects were examined elsewhere than in the hospital Zadig's dynamometer was employed (Zadig 1963).

Enlargement of the patella and its mobility was recorded as well as tenderness across the patella and crepitations in the knee joint.

Radiographs were taken of both knee joints including frontal, lateral and axial projections on the injured side, two oblique projections were taken as well. For loading the patellofemoral joint while the axial projection was taken the subject was standing with the patella to be examined resting against a support mounted on a special examining stand and with the knee in a semi flexed position (Ahlback 1968). Other exposures were taken with the subject in a recumbent position. As Professor Sven Scheller planned the radiographic examination which was carried out by assistants at The Roentgen Department I Sahlgren's hospital. Recording and assessment of the radiographic findings were performed by the author in conjunction with As Professor Scheller.)

Appraisal of the consolidation of the fracture, fibrous union and pseudarthrosis was included in the radiographic analysis. Cerclage breakage was recorded as well as articular surface steps, enlargement of the patella, calcium bodies and bone resembling tissue in the surrounding area and formation and development of osteoarthritis. For the estimation of osteoarthritis the most important factors were changes of the structure—deformation of articular surfaces, presence of cysts and subchondral sclerosis—and a reduced joint space. The presence of osteophytes was not sufficient evidence for osteoarthritis to be diagnosed. A source of error could exist as the femorotibial joint—as opposed to the patellofemoral joint—was not examined during weight bearing of the knee. Osteoarthritis was recorded and classified according to Kellgren & Lawrence (1957) and Kellgren (1963).

Fig. 7 Restricted range of mobility in 27 subjects after patellar fracture

could be measured. The range of mobility of the injured knee was normal in 244 subjects (90%). Restricted range of mobility was found in 27 subjects (10%). Deficiency of extension was recorded in 15 subjects (6%). Eight of these had moderate and seven considerable deficiency. The flexion was restricted in 26 subjects (10%). Out of these 14 had moderate and 12 considerable restriction. Both the deficiency of extension and the bending capacity to a flexed position of less than 120 degrees were recorded in 14 subjects (Fig. 23).

Out of 27 subjects with restricted range of mobility 21 (78%) were older than 60 years of age. Operation had been performed on 16 subjects (60%). The median period of immobilization in plaster 6.5 weeks was exceeded in 6 subjects (33%) who were surgically treated.

The circumference of the thighs was regarded as equal if the difference in the values measured was nil or less than 1 cm. If the circumference of the thigh was reduced by at least 1 cm atrophy of the quadriceps musculature was assumed. Atrophy was assessed as moderate if the reduction was less than 2 cm and considerable if the reduction was at least 2 cm. The circumference of the thighs was equal in 185 subjects (68%). Atrophy of the injured side was moderate in 34 (14%) and considerable in 27 subjects (10%). The circumference of the thigh of the injured side was increased in 21 subjects (8%).

The extension force of the knees was regarded as equal if the same value including a decrease or increase of 10 per cent was obtained for both sides. The extension force of the injured side was considered to be reduced if the reduction was more than 10 per cent and to be augmented if the increase was more than 10 per cent. The reduction of force was classified as moderate if the reduction was less than 30 per cent and considerable if the reduction was at least 30 per cent. Equal force was measured in 150 subjects (55%). Moderate reduction of force was noted in 64 (24%) and considerable in 33 subjects (13%). In 22 subjects (8%) the force of the extensor apparatus of the injured knee was increased.

Only in exceptional cases did the force of the extensors exceed 80 kg. The force of the extensors in the healthy knee varied with age and sex as shown

Fig 21 Subjective symptoms of 49 subjects who merely filled up the questionnaires

Fig 22 Severe pain and/or subjectively experienced considerable impairment of function in 59 subjects after fracture of the patella

pain or subjectively experienced considerable impairment of function (Fig 21)

Both severe pain and subjectively experienced considerable impairment of function were stated by 32 subjects (Fig 22)

The occupation of 243 subjects (76%) was the same or similar to that before the injury. The conditions of living of 61 subjects (10%) irrespective of the injury had changed. Most of these had received their old age pension. 16 subjects (5%) had received a disablement pension or had changed over to lighter work owing to the injury. Of these eight had temporary or lifelong compensation.

### Objective Signs (271 subjects)

The range of mobility of the injured knee was considered as normal if there was no deficiency of extension and if the knee could be flexed to at least 120 degrees. It was considered as restricted if there was deficiency of extension and/or the bending capacity to a flexed position of less than 120 degrees could be measured. The restriction was regarded as moderate if the deficiency of extension was less than or 10 degrees and/or the bending capacity could be measured to a flexed position of less than 120 degrees but more than 90 degrees. It was regarded as considerable if the deficiency of extension exceeded 10 degrees and/or the bending capacity to a flexed position of 90 degrees or less.

Fig. 23. Restricted range of mobility in 27 subjects after patellar fracture

could be measured. The range of mobility of the injured knee was normal in 244 subjects (80%). Restricted range of mobility was found in 27 subjects (10%). Deficiency of extension was recorded in 15 subjects (6%). Eight of these had moderate and seven considerable deficiency. The flexion was restricted in 26 subjects (10%). Out of these 14 had moderate and 12 considerable restriction. Both the deficiency of extension and the bending capacity to a flexed position of knee less than 120 degrees were recorded in 14 subjects (Fig. 23).

Out of 27 subjects with restricted range of mobility, 21 (78%) were older than 60 years of age. Operation had been performed on 16 subjects (60%). The median period of immobilization in plaster 6.5 weeks was exceeded in 6 subjects (34%) who were surgically treated.

The circumference of the thighs was regarded as equal if the difference in the values measured was nil or less than 1 cm. If the circumference of the thigh was reduced by at least 1 cm atrophy of the quadriceps musculature was assumed. Atrophy was assessed as moderate if the reduction was less than 2 cm and considerable if the reduction was at least 2 cm. The circumference of the thighs was equal in 183 subjects (69%). Atrophy of the injured side was moderate in 38 (14%) and considerable in 27 subjects (10%). The circumference of the thigh of the injured side was increased in 21 subjects (8%).

The extension force of the knees was regarded as equal if the same value including a decrease or increase of 10 per cent was obtained for both sides. The extension force of the injured side was considered to be reduced if the reduction was more than 10 per cent and to be augmented if the increase was more than 10 per cent. The reduction of force was classified as moderate if the reduction was less than 30 per cent and considerable if the reduction was at least 30 per cent. Equal force was measured in 150 subjects (55%). Moderate reduction of force was noted in 64 (24%) and considerable in 33 subjects (13%). In 21 subjects (8%) the force of the extensor apparatus of the injured knee was increased.

Only in exceptional cases did the force of the extensors exceed 80 kg. The force of the extensors in the healthy knee varied with age and sex as shown

Fig 24 Mean values of the force of the extensors in the knee of the uninjured side of 271 subjects

in Fig 24, in which the mean values are given for males and females in the various age groups

The rate of considerable reduction of extension force was the same for subjects younger and older than 60 years of age. Considerable reduction of force was found in 20 (23%) of 88 subjects whose injury caused loss of active extension and in 6 (5%) of 114 subjects whose capability of extension was preserved despite the injury. Considerable reduction of force was found in 19 (23%) subjects with the fragments of fracture dislocated at least 4 mm and in 16 (8%) with a diastasis less than 4 mm ( $p < 0.01$ ). Considerable reduction of force was found in 23 (26%) operated and 12 (7%) non operated subjects ( $p < 0.01$ ). Out of the 23 subjects operated upon 16 were subjected to osteosynthesis three to partial patellectomy and four to total patellectomy (26%, 13% and 100% of the respective follow up series).

With an equally large circumference of the thighs great deviations in the extension force could be obtained. When the circumference of both thighs was the same the force measured in one subject could be increased by 20 per cent in the injured leg and in another reduced by 60 per cent. The extension force was reduced in 77 (42%) of the 185 subjects in whom no atrophy was diagnosed. On the other hand there was no subject who had considerable atrophy and increased extension force in the same leg.

The extension force was reduced in 25 (93%) of the 27 subjects who had restricted range of mobility of the injured knee.

B

Fig. 5 Longitudinal lateral fracture of the patella (A) treated with immobilization in plaster (B) shows fibrous union 2 years later (The late result was good)

### Radiographic Findings (246 subjects)

2, subjects were clinically but not radiographically examined 19 were older than 60 years 22 were not inconvenienced by the knee injury whilst three maintained that they had persisting disability owing to the injury Four elderly subjects who were free from symptoms had restricted range of mobility of the injured knee joint The circumference of the thighs was equal in all the 2, subjects Six subjects three of whom were free from symptoms had reduced extension force of the injured knee

Union of the fracture fibrous union pseudarthrosis articular surface steps and enlargement of the patella could be established by radiographic evidence in all the subjects except four on whom total patellectomy had been performed In 221 subjects (91%) the fracture had united

Fibrous union was established in 15 subjects (6%) Fig. 25 Out of these twelve had a longitudinal lateral fracture (Table 17) All 15 subjects were treated non-operatively

Pseudarthrosis was established in 6 subjects (3%) The fact that they had pseudarthrosis was unknown to all of them Four were treated non-operatively and two operatively (Table 17)

Table 17 Distribution of various types of fracture among 47 radiographically examined subjects having had patellar fractures ending in fibrous union pseudarthrosis and articular surface steps The figure in brackets indicates operatively treated cases

D

Fig 26 Comminuted fracture of the patella (A-B) treated non operatively. Six years later the patella was enlarged (C) compared with the opposite side (D) (The late result was excellent )

Out of the radiographically examined subjects 51 were operatively treated by application of a metal wire. In 46 cases the wire was intact but in five it had broken in one or two places.

A step in the articular surface of the patella of 1 mm or more was established in 40 subjects (17%). Table 17. Out of these 22 were not and 18 were subjected to surgery. In 15 cases osteosynthesis was performed with a stainless steel wire inserted through longitudinally drilled holes.

Enlargement of the patella was considered to exist if an increase of width of at least  $\frac{1}{2}$  cm could be measured on the radiograph (Fig 26). 39 (17%) had

Fig. 7 Transverse fracture of the patella with a split lower pole (A) treated with osteosynthesis with a metal wire through longitudinally drilled holes. B and C seven years later show bone resembling tissue in the surroundings of the patella and articular surface step. (The late result was poor.)

enlargement of the patella of the injured side. Out of these 22 were non-operatively and 17 operatively treated, constituting 13 and 21 per cent of the respective follow-up series. Enlargement of the patella was established after both osteosynthesis and partial excision.

Sometimes calcium bodies in the surroundings of the patella were visible on the radiograph, and pretty frequently bone resembling tissue could be seen in the patellar ligament and the quadriceps tendon (Fig. 27). These kinds

time of injury

Fig. 30 Osteoarthritis of the injured knee as well as of the patellofemoral joint of the opposite side at the follow up examination and osteoarthritis of the injured knee at the time of injury

femoral and femorotibial joints of the same knee and furthermore develop bilaterally (Hilbich 1969) and as osteoarthritis had been diagnosed in the primary series a diagram could be traced (Fig. 30) showing the cases in which it could be assumed that the osteoarthrotic changes in the patellofemoral joint of the injured side had developed as a result of the injury. There remained ten cases as stated in the diagram.

However when patellofemoral osteoarthritis was observed on the injured side it was also possible to establish whether the osteoarthrotic changes had become increased in comparison with the time of injury and with the opposite side. This type of progressive osteoarthritis was diagnosed in 24 subjects (10%) none of whom had osteoarthritis in the femorotibial joint of the injured side.

Osteoarthritis—irrespective of the genesis and the location—depended on the age of the subjects at the follow up examination. Osteoarthritis of the injured knee was found in 42 (39%) of those over 60 years of age and in 29 (41%) of those under ( $p < 0.01$ ). Osteoarthritis of the knee occurred twice as often in females as in males. Osteoarthritis of the injured patellofemoral joint was diagnosed in 28 subjects (25%) who were injured in a traffic accident or

Fig 28 Osteoarthritis of the injured knee of 71 subjects after patellar fracture

of changes were present in 67 subjects (27%) Out of these 56 were surgically treated The radiographic examination revealed these changes in almost all of those who had sustained partial or total excision of the patella

Osteoarthrotic changes were not diagnosed on the basis of slight formation of osteophytes and a normal height of the joint space without changes in the structure of the articular surface Slight osteoarthritis was established if the formation of osteophytes was moderate and the joint space was slightly reduced with or without structural changes Moderate osteoarthritis was present when the formation of osteophytes was moderate or pronounced the height of the joint space was moderately reduced and structural changes such as deformation of the articular surfaces and subchondral sclerosis were moderate Considerable osteoarthritis was diagnosed when the formation of osteophytes and the reduction of the joint space were pronounced with a definite deformation of the articular surfaces with sclerosis and formation of cysts in the subchondral bone

Osteoarthrotic changes in the injured patellofemoral joint were observed in 55 subjects (22%) Out of these 33 had slight changes 15 moderate and seven considerable Osteoarthrotic changes in the femorotibial joint of the injured side were established in 43 subjects (18%) Out of these 28 had slight changes eleven moderate and four considerable The number of subjects with osteoarthritis of the injured knee totalled 71 (29%) which is illustrated in Fig 28

In the patellofemoral joint of the opposite side osteoarthrotic changes were observed in 19 subjects (8%) Out of these seven had slight changes eight moderate and four considerable In the femorotibial joint of the opposite side osteoarthrotic changes were observed in 23 subjects (9%) Out of these 16 had slight changes six moderate and one considerable The total number of subjects with osteoarthritis of the opposite side was 27 (11%) as demonstrated in Fig 29

Radiographs taken at the time of injury revealed osteoarthrotic changes in the injured knee joint in 35 subjects (9%)

As degenerative osteoarthritis may occur simultaneously in both the patello

Table 18 Subjective symptoms correlated with various objective signs

Subjective symptoms	Objective signs				
	Restricted range of mobility	Considerable reduction of force	Fibrous union and pseudarthrosis	Articular surface step $\geq 1$ mm	Osteoarthrosis
No pain	7 (6%)	6 (1%)	10 (43%)	1 (30%)	19 (70%)
Mild	3 (11%)	4 (11%)	3 (14%)	9 (70%)	16 (52%)
Moderate	3 (11%)	6 (17%)	6 (29%)	10 (70%)	11 (41%)
Severe	14 (52%)	19 (57%)	2 (9%)	9 (26%)	28 (49%)
Total	27 (100%)	35 (100%)	21 (100%)	40 (100%)	74 (100%)

Out of the 27 subjects with a restricted range of mobility 22 (82%) had osteoarthrosis at the primary or the follow up radiographic examination. Out of the 34 subjects with a considerable reduction of force 21 (60%) had osteoarthrosis at the primary or the follow up radiographic examination.

### Classification of results

The result was considered *excellent* if the subject was free from discomfort without pain or subjectively experienced impairment of function with a normal range of mobility of the knee joint and with equal force in the extensor apparatus of both knees. The result was considered *poor* if the injury alone could be assumed to be the cause of pain at rest and/or pain during all kinds of activity. Furthermore the result was regarded as *poor* if the injury alone could be assumed to be the cause of at least two of the following three symptoms and signs:

1. Subjectively experienced impairment of function corresponding to a score exceeding 4 and 6 points respectively.
2. Insufficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less.
3. Reduction of force of the extensor apparatus of the knee exceeding 30 per cent of the force of the uninjured knee.

In all the other cases the result was considered *good*. Subjects with a good result formed a heterogeneous group. In this group were included in addition to those with a good result on account of the injury also those with a poor result that was not ascribable to the injury but instead probably caused by

by fall from height and 29 (19%) injured by other modes ( $p>0.05$ ). After open fracture, osteoarthritis of the injured patellofemoral joint was observed in 9 subjects (60%) and after closed fracture in 46 subjects (20%) ( $p<0.01$ ). After comminuted fracture osteoarthritis of the injured patellofemoral joint was diagnosed in 17 subjects (42%) and after other types of fracture in 38 (19%) ( $p<0.01$ ). Osteoarthritis of the injured patellofemoral joint occurred twice as often after operative as after non operative treatment (35% and 16% of the respective follow up series) ( $p<0.01$ ). Osteoarthritis of the femorotibial joint of the injured side occurred just as frequently after operative as after non operative treatment. The frequency of osteoarthritis was as large after osteosynthesis as after partial patellectomy (32% and 35% of the respective follow up series). All four subjects who were radiographically examined after total patellectomy had osteoarthrotic changes in the femoral component of the injured patellofemoral joint.

There was no increase in the frequency of osteoarthritis of the patellofemoral joint because of fibrous union and pseudarthrosis (24% contra 22% in the other series).

Osteoarthritis of the patellofemoral joint was found in 16 subjects (40%) with a step in the articular surface of the patella of 1 mm or more and in 35 (17%) in the other series ( $p<0.01$ , four cases of total patellectomy excluded). Only seven of these 16 subjects had osteoarthrotic changes which could be assumed to have been formed or developed as a result of the injury. Regarding only those with osteoarthrotic changes of the patellofemoral joint assumed to have been formed or developed as a result of the injury the frequency of osteoarthritis was insignificantly higher in those with a step in the articular surface of the patella of 1 mm or more as compared with the other series ( $p>0.05$ ). Osteoarthritis of the injured patellofemoral joint was insignificantly higher when there was enlargement of the patella (28% contra 22% in the other series after excluding the cases of total patellectomy) ( $p>0.05$ ). Osteoarthritis of the injured knee was established in 28 (42%) of the 67 subjects who had calcium bodies and bone resembling tissue in the surrounding areas of the patella and 43 (24%) in the other series ( $p<0.01$ ).

### *Correlations*

Pain connected with various objective signs is stated in Table 18.

The subjects who had a restricted range of mobility and considerable reduction of force without pain were elderly subjects with osteoarthritis irrespective of the injury. Half the number of subjects with fibrous union and pseudarthrosis felt no pain. Some subjects with both osteoarthritis and an articular surface step of 1 mm or more were free from pain.

Table 18 Subjective symptoms correlated with various objective signs

Subjective symptoms	Objective signs				
	Restricted range of mobility	Considerable reduction of force	Fibrous union and pseudarthrosis	Articular surface step $\geq 1$ mm	Osteoarthrosis
No pain	7 (26%)	6 (15%)	10 (43%)	10 (30%)	19 (54%)
Slight	3 (11%)	4 (11%)	3 (14%)	9 (27%)	16 (45%)
Moderate	3 (11%)	6 (15%)	6 (26%)	10 (30%)	8 (22%)
Severe	14 (50%)	19 (55%)	2 (8%)	9 (27%)	9 (24%)
Total	27 (100%)	35 (100%)	21 (100%)	40 (100%)	52 (100%)

Out of the 27 subjects with a restricted range of mobility 22 (82%) had osteoarthrosis at the primary or the follow up radiographic examination. Out of the 35 subjects with a considerable reduction of force 21 (60%) had osteoarthrosis at the primary or the follow up radiographic examination.

### Classification of results

The result was considered *excellent* if the subject was free from discomfort without pain or subjectively experienced impairment of function with a normal range of mobility of the knee joint and with equal force in the extensor apparatus of both knees. The result was considered *poor* if the injury alone could be assumed to be the cause of pain at rest and/or pain during all kinds of activity. Furthermore the result was regarded as *poor* if the injury alone could be assumed to be the cause of at least two of the following three symptoms and signs:

1. Subjectively experienced impairment of function corresponding to a score exceeding 4 and 11 points respectively.
2. Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less.
3. Reduction of force of the extensor apparatus of the knee exceeding 30 per cent of the force of the uninjured knee.

In all the other cases the result was considered *good*. Subjects with a good result formed a heterogeneous group. In this group were included in addition to those with a good result on account of the injury also those with a poor result that was not ascribable to the injury but instead probably caused by

another disease. If it had been possible in these cases to assess the real result of the injury one or other of the subjects might have been referred either to the group excellent or to the group poor results

Of those who merely answered questionnaires none were referred to the group poor results. However it cannot be excluded that one or other might have been included in the group poor results if a complete examination had been carried out

Of those who were clinically examined but not radiographically, two subjects were included in the poor results. Possibly one of these or both could have been included in the group good results after complementary radiographic examinations which could have given evidence of osteoarthritis not being connected with the injury

Pain at rest and/or pain during all kinds of activity was noted in 42 subjects. In 16 of these the pain could depend on osteoarthritis of the knee joint but with no relation to the injury. A further seven had pain which could be caused by some other injury or disease. The remaining 19 subjects were included in the group poor results owing to patellar fracture (Fig 31)

Impairment of function corresponding to a score exceeding 4 and 8 points respectively was subjectively experienced by 49 subjects. In 26 of these the impairment of function could depend on osteoarthritis, some other disease or injury without any sure relation to the patellar fracture. In the group poor results owing to patellar fracture the remaining 23 subjects were included (Fig 31)

Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less was observed in 17 subjects. Eight of these had a restricted range of mobility which could depend on some other injury or disease especially osteoarthritis

Reduction of force of the extensor apparatus of the injured knee exceeding 30 per cent of the force of the uninjured knee was recorded in 35 subjects. Out of these 16 subjects had reduced force which could depend on other disease or injury especially osteoarthritis

Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less and/or reduction of the force of the extensor apparatus of the knee exceeding 30 per cent was established in 46 subjects. To the group poor results owing to fracture of the patella 22 of these were included (Fig 31)

A total of 73 subjects had one or several subjective symptoms or objective signs according to the criteria on which a poor result was based (Fig 31)

Excellent results were achieved in 145 (45%) and good results in 150 subjects (47%). The results were poor in 25 (8%) subjects. The distribution of the results among males and females is indicated in Fig 32

Fig 31 Subjective symptoms and objective signs of 73 subjects with a poor result in some respect. The figures in brackets indicate the subjects who according to the classification were considered to belong to the group poor results owing to patellar fracture.

Fig 3 Late results of patellar fractures in males and females

There was no difference in the distribution of the results among those over 60 years of age as compared with those under (Fig 33).

After patellar fractures caused by traffic accidents or falls from height poor results were more common than after patellar fractures caused by falls in the same plane and by direct blows ( $p < 0.01$ ) (Fig 34).

There were poor results of open fractures in 30 per cent and of closed fractures in 6 per cent ( $p < 0.01$ ) (Fig 35).

In subjects who had a concomitant injury the result was more often poor as compared with those who had no other injury ( $p < 0.01$ ) (Fig 36).

The results of all types of transverse fracture and comminuted fractures

another disease. If it had been possible in these cases to assess the real result of the injury, one or other of the subjects might have been referred either to the group excellent or to the group poor results.

Of those who merely answered questionnaires, none were referred to the group poor results. However, it cannot be excluded that one or other might have been included in the group poor results if a complete examination had been carried out.

Of those who were clinically examined, but not radiographically, two subjects were included in the poor results. Possibly one of these or both could have been included in the group good results after complementary radiographic examinations which could have given evidence of osteoarthritis not being connected with the injury.

Pain at rest and/or pain during all kinds of activity was noted in 12 subjects. In 16 of these the pain could depend on osteoarthritis of the knee joint but with no relation to the injury. A further seven had pain which could be caused by some other injury or disease. The remaining 19 subjects were included in the group poor results owing to patellar fracture (Fig. 31).

Impairment of function corresponding to a score exceeding 4 and 6 points respectively was subjectively experienced by 49 subjects. In 26 of these the impairment of function could depend on osteoarthritis, some other disease or injury without any sure relation to the patellar fracture. In the group poor results owing to patellar fracture the remaining 23 subjects were included (Fig. 31).

Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less was observed in 17 subjects. Eight of these had a restricted range of mobility which could depend on some other injury or disease, especially osteoarthritis.

Reduction of force of the extensor apparatus of the injured knee exceeding 30 per cent of the force of the uninjured knee was recorded in 35 subjects. Out of these 16 subjects had reduced force which could depend on other disease or injury, especially osteoarthritis.

Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less and/or reduction of the force of the extensor apparatus of the knee exceeding 30 per cent was established in 46 subjects. To the group poor results owing to fracture of the patella 22 of these were included (Fig. 31).

A total of 73 subjects had one or several subjective symptoms or objective signs according to the criteria on which a poor result was based (Fig. 31).

Excellent results were achieved in 145 (45%) and good results in 160 subjects (47%). The results were poor in 25 (8%) subjects. The distribution of the results among males and females is indicated in Fig. 32.

Fig 31 Subjective symptoms and objective signs of 73 subjects with a poor result in some respect. The figures in brackets indicate the subjects who according to the classification were considered to belong to the group poor results owing to patellar fracture

Fig 3 Late results of patellar fractures in males and females

There was no difference in the distribution of the results among those over 60 years of age as compared with those under (Fig 33)

After patellar fractures caused by traffic accidents or falls from height poor results were more common than after patellar fractures caused by falls in the same plane and by direct blows ( $p < 0.01$ ) (Fig 34)

There were poor results of open fractures in 30 per cent and of closed fractures in 6 per cent ( $p < 0.01$ ) (Fig 35)

In subjects who had a concomitant injury the result was more often poor as compared with those who had no other injury ( $p < 0.01$ ) (Fig 36)

The results of all types of transverse fracture and comminuted fractures

Fig 33 Late results of patellar fractures in various age groups

Fig 34 Late results of patellar fractures as related to the mode of injury

were equivalent (Fig 37) The result was poor in one subject who had sustained a longitudinal lateral fracture Also after longitudinal medial apical and basal fractures which generally were extra articularly situated the result was poor only in exceptional cases (Fig 37)

When there was only slight separation of the fragments the result was excellent or good in 98 per cent (Fig 38) If the diastasis was considerable suggesting an extensive tear of the lateral expansions the result was poor in 20 per cent

After non operative treatment the result was excellent in 118 subjects (56%) good in 92 (43%) and poor in 2 (1%) After operative treatment it was excellent in 27 subjects (25%) good in 58 (54%) and poor in 23 (21%) Fig 39

The results of various methods of operative treatment are stated in Fig 40

Fig 35 Late results of open and closed patellar fractures

Fig 36 Late results of patella fractures with and without concomitant injuries

Fig 37 Late results of various types of patellar fracture

Fig 38 Late results of patellar fractures with regard to the separation between the fragments

Fig 39 Late results of non operative and operative treatment of patellar fractures

Fig 40 Late results of various methods of operative treatment for patellar fractures

Fig 41 Late results of transverse patellar fractures with a split lower pole treated by means of either osteosynthesis or partial patellectomy

Fig 42 Late results of fibrous union and pseudarthrosis of enlargement of the patella and of presence of calcium bodies and bone resembling tissue in the surrounding area after patellar fracture

After osteosynthesis and partial patellectomy poor results were equally frequent (19% and 18% of the respective follow up series). In none of the cases of total patellectomy was the result excellent.

In transverse fractures with a split lower pole 23 subjects were treated with osteosynthesis with a stainless steel wire inserted through longitudinally drilled holes and 16 with partial patellectomy (Fig 41). The results were poor in 6 subjects (26%) after osteosynthesis and in 2 (12%) after partial patellectomy ( $p > 0.05$ ).

With fibrous union and pseudarthrosis 10 subjects (48%) had an excellent result, 11 (52%) a good and none a poor (Fig 42).

Only one of 22 non-operatively treated subjects who had a persisting step in the articular surface of the patella of 1 mm or more revealed at the follow up examination had a poor result; the result was excellent in 11 (41%) and

Fig 43 Late result in 40 subjects with a persisting step in the articular surface of the patella of 1 mm or more after patellar fracture

good in 12 subjects (54%), Fig 43. Five subjects (28%) of those operatively treated with a persisting step in the articular surface of the patella of 1 mm or more were referred to the group poor results only one achieved an excellent result

The result of enlargement of the patella radiographically verified and of the presence of calcium bodies and bone resembling tissue in the surroundings are indicated in Fig 42

All subjects referred to the group poor results owing to patellar fracture stated that they were not restored when the treatment terminated and that the discomfort continued. When the treatment was ended certificates of disablement were issued to 17 subjects owing to sequelae of the patellar fracture 16 of whom were followed up. Five subjects in this investigation referred to the group poor results were not considered by the insurance companies to have reduced capacity for work exceeding 10 per cent (Table 19)

Table 19 Late results of 16 subjects as classified by insurance companies with regard to compensation for reduced capacity for work after patellar fracture

Compensation	Results			Total
	Excellent	Good	Poor	
No compensation	2	2	1	5
Temporary compensation		1	1	2
Lifelong compensation		1	4	5

## CHAPTER V

### DISCUSSION AND CONCLUSIONS

#### Series

Fracture of the patella strikes subjects of all ages. The mean age in this series was 48 years which is higher than reported by other authors. In conformity with Nummi (1971) the mean age of males was considerably lower as compared with females.

The percentage of injured males was 57 which is less than stated in most other reports.

Several authors state that fracture of the patella occurs in an increasing frequency as a result of traffic accidents. In agreement with Schonbauer (1959) and Nummi the present series does not support this statement. In males younger than 50 years of age traffic accidents however were the most common cause of patellar fracture. The classification of different types of patellar fracture varies with the authors and comparisons are difficult to make. The number of longitudinal lateral fractures was remarkably large probably depending on a careful radiographic examination and furthermore on the fact that the series similar to that of Nummi included ambulant cases. Both the present investigations show—as opposed to an earlier concept—that the longitudinal lateral fracture is a common type of patellar fracture. In conformity with Smilie (1970) it was found that a number of different types of fracture may result from the same mode of injury. From the appearance of the fracture no sure conclusions could be drawn as to the modes of injury.

The injury to the lateral expansions was of decisive importance for selecting the method of treatment. With a diastasis of 4 mm or more the tear of the lateral expansions was so widespread that there was loss of active extension in most of the cases. The operatively treated patients constituted 32 per cent of the entire series. This group was of the same magnitude as that of Nummi (31%).

The post operative complications were few and of the same proportions as those reported by other authors (cf. Nummi 5%). However it is remarkable that no cases of thrombosis or thromboembolism were diagnosed.

Some authors hold the opinion that several days should elapse after the

injury before applying a plaster cast. In this series a plaster cast was applied immediately. As a rule this did not involve any disadvantages. However two patients contracted paralysis of the peroneus after the plaster was applied.

Re operation was rarely necessary. Only in exceptional cases (4 cases) was there reason to remove the metal wire. Nummi reported 62 extirpations of the metal wire frequently done because of pain where the wire had not been tied. The low frequency of extirpation of the metal wire in this series no doubt depended on the twined end of the wire having been recessed into the patella.

Conclusive comparisons with regard to periods of sick leave and compensation for disablement between the various series are frequently difficult to make as the social and economical advantages vary with the different countries. The periods of sick leave in this investigation were equivalent to those of Nummi after both non operative and various types of operative treatment.

At the follow up study it was in conformity with other authors possible to establish that subjective symptoms occurred to a great extent after patellar fracture. As the period of observation was almost nine years and the mean age at the follow up examination was 53 years it is necessary to bear in mind that there may be other reasons for the joint discomfort than the sequelae of patellar fracture.

Restricted range of mobility was found mainly in elderly subjects and in those who had osteoarthritis. Contrary to Ehlert (1963) a long period of immobilization in plaster was not found to prevent the recovery of mobility at long sight.

Measuring of the circumference of the thigh should be combined with recording of the force of the extensors of the knee in order to allow an adequate interpretation of the quadriceps function. This especially applies when the circumference of both legs is equal in size. The figures obtained possibly did not represent the maximal force which according to Clarke *et al* (1950) and Hallen & Lindahl (1967) is reached when the knee joint is flexed through 60–75 degrees. The figures recorded were the same as those obtained from an equivalent age group by other Swedish authors.

As other authors have pointed out the force of the extensors of the knee was often reduced after fracture of the patella and particularly after total patellectomy. The force of the extensor apparatus of the knee is no doubt affected also by factors other than the reduced length of the lever (cf Stener 1969) e.g. painful hydrops of the joint (de Andrade Grant & Dixon 1965) and inflammatory changes (Trelhus 1969). It is possible that the force of extension after healing of the patellar fracture depends on the tear of the lateral expansions at the time of injury.

The theory supported by several authors (cf Schonbauer 1955, J. Bohler 1961, Nummi 1971) that steps in the articular surface of the patella provoke

osteoarthrosis has not been realized in this investigation. An increase in the frequency of osteoarthrosis of the patellofemoral joint assumed to have been formed or developed as a result of the injury was indeed recorded when there was a step of the articular surface amounting to 1 mm or more but the difference in frequency was not significant. Furthermore quite a few subjects with a step in the articular surface of the patella experienced no pain.

Thomson (1942) maintained that enlargement of the patella did not occur after partial patellectomy. In this investigation enlargement of the patella occurred after both partial patellectomy and osteosynthesis and furthermore after both non operative and operative treatment. As opposed to Sørensen (1964) there was no increase in the frequency of osteoarthrosis with enlargement of the patella in this investigation.

Many authors have pointed out that osteoarthrosis may set in after a joint lesion. In this investigation there were possibilities of establishing the development of osteoarthrosis which could be secondary to the injury and of that which could depend on other circumstances.

A rather high frequency of osteoarthrosis of a primary type could be expected as the higher age groups included many females (Hernborg 1969). The frequency of osteoarthrosis as reported in other series is probably too high because no distinction has been made between primary and secondary osteoarthrosis. Nummi agrees that his figures are too high. Sørensen mentions that only in exceptional cases had he access to radiographs taken at the time of injury and thus was unable to assess development of osteoarthrosis. Without doubt however osteoarthrosis may develop as a direct result of the injury. In this series there was an increase in the frequency of osteoarthrosis after open fracture comminuted fracture and operative treatment whilst the choice of operation method seemed to be of secondary importance. Some of the subjects with osteoarthrosis were free from pain.

Poor results were recorded in 8 per cent of the entire series (24/320). In the group poor results Fontaine *et al.* (1965) included 10 per cent (9/78) Vilhger (1961) 4 per cent (3/82) Detmar (1966) 7 per cent (7/104) Struck (1966) 0 per cent (5/82) and Nummi (1971) 8 per cent (32/391).

There was a distinct male predominance among those included in the poor results following patellar fracture. On the other hand, the better results were equivalent with respect to age over and under 60 years. The mode of injury and other circumstances connected with the trauma were essential. Traffic injury and fall from height open fracture and concomitant injury were factors which contributed to a poor result.

Excellent and good results of longitudinal apical and basal fractures were achieved to a large extent. In these fractures the injury to the lateral expansions was often slight. This investigation does not support the opinion held

for instance by de Palma (1954) that longitudinal lateral fractures should be treated surgically in order to avoid future discomfort. Despite the fact that fibrous union was most common in longitudinal lateral fractures the frequency of poor results was low.

Excellent, good and poor results were recorded to the same extent in transverse types of fracture as in comminuted fractures. The type of fracture seemed to be of secondary importance as compared with the injury to the lateral expansions.

In conformity with other authors, this series revealed to a great extent excellent and good results of the fractures to which non operative treatment was applicable. In this series poor results were noted in 1 per cent (2/212) of fractures treated non operatively. In the group poor after non operative treatment Fontaine *et al* included 5 per cent (1/20), Villiger 5 per cent (1/21), Detmar 11 per cent (3/27), Struck 4 per cent (2/51) and Nummi 4 per cent (10/236).

In the cases treated operatively, the results were less satisfactory as expected. Poor results in this series amounted to 21 per cent (23/108). The corresponding figures of poor results in other series are lower. Fontaine *et al* reported 12 per cent (7/58), Villiger 3 per cent (2/61), Detmar 5 per cent (4/77), Struck 10 per cent (3/31) and Nummi 14 per cent (22/155).

However the results cannot simply be compared. The late results of a joint lesion can be assumed to depend on other conditions than the injury and often the extent of consideration taken to this fact is not clearly expressed. Furthermore the methods of analysis and the criteria vary with different authors.

Excellent, good and poor results were recorded to the same extent after methods used for restoration of normal anatomy and after partial patellectomy. Too few patients were subjected to total patellectomy for any conclusions to be drawn as to the value of this method of operation. The patients on whom total excision of the patella was performed all had open fractures. The most common method of operation employed in attempting to restore the anatomy was stainless steel wire inserted through longitudinally drilled holes according to Payr. It was used both for transverse and comminuted fractures. Operative treatment of transverse fractures with a split lower pole could be performed either by osteosynthesis with a stainless steel wire inserted through longitudinally drilled holes or by partial patellectomy. In the follow up study there were 23 and 16 subjects respectively who had been operated on by the use of these methods. Partial patellectomy tended to give better results of this particular type of fracture as compared to osteosynthesis but the groups of patients were small and the differences not significant.

In no case of fibrous union and pseudarthrosis were the late results poor a fact experienced also by Nummi.

A step in the articular surface of the patella of 1 mm or more did not affect the late results of non operatively treated cases. Nor did a persistent step in the articular surface of the patella of 1 mm or more significantly increase the frequency of poor results of operatively treated cases. This may imply that it is not essential to attain exact reposition and that a difference of level of 2-3 mm between the fragments can be accepted and treated non operatively if there is no other indication of operation.

Enlargement of the patella did not affect the late results. Nor did the enlargement provoke osteoarthritis and consequently this finding is of little clinical importance. Calcium bodies in the surroundings of the patella and bone resembling tissue in the quadriceps tendon and in the patellar ligament gave poor results approximately to the extent expected in view of the fact that most of the patients had been treated by surgery. The frequency of osteoarthritis with these above mentioned changes was also just as high as that obtained after operative treatment. The clinical importance of the changes is probably insignificant.

Finally it is remarkable that all the subjects with a poor result pointed out that they were not restored at the end of the treatment and that the discomfort continued.

### / Conclusions

Certain misgivings are involved with fracture of the patella inasmuch as persistent disability may result in the form of pain subjectively experienced reduction of function restricted range of mobility reduced force of extension of the knee and osteoarthritis. On the basis of a follow up study of 320 patients subjected to patellar fracture the following was found.

- 1 The mechanism of injury and the severity of the trauma affect the late results of patellar fracture. In traffic accidents and falls from height and also in open fractures and concomitant injuries there will be a greater risk of a poor result.
- 2 Various types of fracture may result from the same mode of injury. A particular type of fracture is no true indication of the mode of injury. Nor is it generally possible to give a sure statement of the prognosis on the basis of the type of fracture. However there is a good prognosis for longitudinal apical and basal fractures in all probability depending on the injury to the lateral expansions being slight in most of these fractures.
- 3 The patient's capacity for extension of the knee the separation and the difference of level between the fragments are factors to be borne in mind when deciding whether non operative or operative treatment shall follow. When the extension capacity is preserved the separation of fragments is

for instance, by de Palma (1954) that longitudinal lateral fractures should be treated surgically in order to avoid future discomfort. Despite the fact that fibrous union was most common in longitudinal lateral fractures the frequency of poor results was low.

Excellent, good and poor results were recorded to the same extent in transverse types of fracture as in comminuted fractures. The type of fracture seemed to be of secondary importance as compared with the injury to the lateral expansions.

In conformity with other authors this series revealed to a great extent excellent and good results of the fractures to which non operative treatment was applicable. In this series poor results were noted in 1 per cent (2/212) of fractures treated non operatively. In the group poor, after non operative treatment Fontaine *et al* included 5 per cent (1/20) Villiger 5 per cent (1/21), Detmar 11 per cent (3/27) Struck 4 per cent (2/51) and Nummi 4 per cent (10/236).

In the cases treated operatively the results were less satisfactory as expected. Poor results in this series amounted to 21 per cent (23/108). The corresponding figures of poor results in other series are lower. Fontaine *et al* reported 12 per cent (7/58) Villiger 3 per cent (2/61) Detmar 5 per cent (4/77) Struck 10 per cent (3/31) and Nummi 14 per cent (22/155).

However the results cannot simply be compared. The late results of a joint lesion can be assumed to depend on other conditions than the injury and often the extent of consideration taken to this fact is not clearly expressed. Furthermore the methods of analysis and the criteria vary with different authors.

Excellent, good and poor results were recorded to the same extent after methods used for restoration of normal anatomy and after partial patellectomy. Too few patients were subjected to total patellectomy for any conclusions to be drawn as to the value of this method of operation. The patients on whom total excision of the patella was performed all had open fractures. The most common method of operation employed in attempting to restore the anatomy was stainless steel wire inserted through longitudinally drilled holes according to Payr. It was used both for transverse and comminuted fractures. Operative treatment of transverse fractures with a split lower pole could be performed either by osteosynthesis with a stainless steel wire inserted through longitudinally drilled holes or by partial patellectomy. In the follow up study there were 23 and 16 subjects respectively who had been operated on by the use of these methods. Partial patellectomy tended to give better results of this particular type of fracture as compared to osteosynthesis but the groups of patients were small and the differences not significant.

In no case of fibrous union and pseudarthrosis were the late results poor a fact experienced also by Nummi.

Pestoration of normal anatomy is recommended for transverse fractures with two large fragments and comminuted fractures when the articular surface can be restored

Repair of the quadriceps apparatus retaining one large fragment is recommended in transverse fractures with a split upper or lower pole and in comminuted fractures if the articular surface cannot be restored and there is a large fragment including more than half of the patella

Total excision of the patella never seems to be a treatment of choice but is recommended in exceptionally severe cases e.g. open comminuted fractures or when other methods of treatment have failed

Irrespective of the operation method selected it is essential that the tear of the lateral expansions be identified and that the anatomy be accurately restored

The post operative procedure is the same irrespective of the operation method elected Immobilization in a plaster cast with the knee flexed through 5-10 degrees during 6-7 weeks is indicated The patient should be instructed to practice active exercise of the quadriceps muscles (Svantesson 1971) When the quadriceps muscles can be contracted leg raising is instituted Weight bearing and mobilization on crutches as protecting support are permitted when the patient can lift his leg When the plaster cast has been discarded the patient should be instructed how to practice active exercises Primarily this includes isometric and later also isotonic extension and flexion exercises—in the beginning without and later with increasing resistance The exercises should be carried out under the supervision of a physiotherapist

3-4 mm or less, and the difference of level is 2-3 mm or less excellent and good late results can be expected after non operative treatment. The prognosis is less good after operative than after non operative treatment no doubt, owing to the more serious injury necessitating operative treatment. The choice of operation method is probably of secondary importance as compared with the mode of injury and other circumstances involved with the trauma.

- 4 After a joint lesion such as a fracture of the patella subjective symptoms and objective signs may depend—particularly with increasing age—on circumstances other than sequelae of the injury especially osteoarthritis.
- 5 It is difficult to come to any definite conclusions when comparing between different series owing to the varying criteria used for classification. However after perusal of the literature on the subject and after study of this series, there has not been any reason to recommend the introduction of another method of treatment nor to advise against the use of any of the methods which were applied in this series.

### Suggestion of treatment

*On the basis of the literature and this series the following is recommended*

#### *Non Operative Treatment*

The patient's capacity for lifting his leg with the knee extended, the extent of separation and the difference of level between the fragments must be considered when deciding between non operative and operative treatment. When the extension capacity of the knee is preserved, the diastasis is 3-4 mm or less and the step in the articular surface is 2-3 mm or less non operative treatment is advised. If there is loss of active extension of the knee and the diastasis is less than 4 mm the patient should be hospitalized and the joint should be punctured pending the development. A severe tear of the lateral expansions involved with this diastasis is most unlikely.

In non operative treatment immobilization in a plaster cast during four weeks is generally sufficient, the time of which can be reduced in cases of longitudinal fracture. The patient should be instructed to practice active exercise of the quadriceps muscles. Weight bearing is permitted. Crutches as protecting support are recommended.

#### *Operative Treatment*

Loss of active extension of the knee and a diastasis of more than 3-4 mm and a step in the articular surface of the patella of more than 2-3 mm are indications for operation.

bilized in a plaster cast was two months and of those operated on four months. The median period of sick leave was insignificantly shorter after partial patellectomy than after osteosynthesis.

Follow up examination was carried out 5-12 years after the injury. The mean time of observation was 8.9 years. The late results of 320 subjects—totalling 91 per cent of those alive at the time of the follow up—were reported. A questionnaire was filled up. A clinical examination was performed on 271 subjects. Pain and subjectively experienced impairment of function were recorded as well as the range of mobility of the knee joint, the circumference of the thigh and the force of the extensors of the knee. The radiographic examination of both knee joints in 246 subjects gave evidence of union, fibrous union, pseudarthrosis, cerclage breakage, step in articular surface, enlargement of the patella, calcium bodies and bone resembling tissue in the surroundings and formation and development of osteoarthritis.

70 per cent of the subjects were satisfied and stated that the injury had not caused persisting discomfort. 59 per cent of the non-operatively and 30 per cent of the operatively treated subjects felt no pain. A normal function was subjectively experienced by 78 per cent of the non-operatively and 36 per cent of the operatively treated subjects.

Deficiency of extension of the knee was recorded in 6 per cent and bending capacity to a flexed position of less than 120 degrees was noted in 10 per cent. The circumference of the thigh of the injured leg was reduced in 24 per cent. The extension force of the knee was reduced in 37 per cent. Reduction of force occurred to a greater extent when the separation between the fragments measured 4 mm or more.

Fibrous union was more often found in longitudinal lateral fractures than in other types of fracture but caused no poor results. Pseudarthrosis was recorded in 3 per cent and occurred after both non-operative and operative treatment; no case of poor results was noted. A step in the articular surface of the patella of 1 mm or more was observed in 40 subjects (17%), half of whom were operated upon, the majority according to the method of osteosynthesis with a stainless steel wire inserted through longitudinally drilled holes. There was possibly no relation between a step in the articular surface and formation and development of osteoarthritis in the patellofemoral joint caused by the injury. Enlargement of the patella as well as calcium bodies and bone resembling tissue in the patellar surroundings did not seem to be of clinical importance. Formation and development of osteoarthritis could result from the injury but the occurrence of osteoarthritis was often independent of the injury and was mainly seen in females in advanced ages.

Excellent results were achieved in 45 per cent and good results in 47 per cent while poor results were noted in 8 per cent. There was a decided male

## CHAPTER VI

### SUMMARY

The series includes 416 patients who were radiographically examined in Göteborg during the period 1959-1964 because of injury to the knee and the diagnosis was a fresh fracture of the patella

57 per cent were males and 43 per cent females the mean age was 42 and 54 years, respectively The maximum of frequency for males was reached between the ages of 30 and 39 years, and for females between 60 and 69 years

The most common mode of injury was a fall in the same plane (54%) the next common various types of traffic accidents (28%) In 6 per cent there was an open fracture and in 15 per cent a concomitant injury which in almost half of the cases involved the lower extremities

Transverse fractures were diagnosed in 34 per cent comminuted in 16 per cent longitudinal lateral in 22 per cent and others including longitudinal medial apical and basal fractures in 28 per cent The different modes of injury exhibited a large variety of fractures 51 per cent of the fractures were non dislocated and in a total of 70 per cent the diastasis was less than 4 mm The step in the articular surface in this dislocation was nearly always less than 3 mm A diastasis of at least 4 mm was established in 30 per cent A loss of active function of the quadriceps muscles was found in 33 per cent

Non operative methods of treatment were considered advisable in preserved extension capacity of the knee diastasis less than 4 mm and a step in the articular surface less than 3 mm 287 fractures in 282 patients (68%) were treated non operatively usually with immobilization in a plaster cast during 3-5 weeks 135 fractures in 134 patients (32%) were subjected to surgery The most common method of operation was osteosynthesis with a stainless steel wire inserted through longitudinally drilled holes Partial patellectomy was the next common method of operation while total excision of the patella was performed only exceptionally All the methods of operation were followed by immobilization in plaster the median period of which was 6.5 weeks Complications occurred in 5 per cent Re operation was performed in 5 per cent The most common re operation was mobilization of the patella performed owing to restricted mobility of the knee joint after the plaster cast had been discarded

The median period of sick leave of non operatively treated patients immo

predominance among those with poor results. Injury owing to traffic accidents and fall from height open fracture and concomitant injury entailed a greater risk of a poor result. After longitudinal, apical, and basal fractures, in which the tear of the lateral expansions was frequently slight, the late results were better than after transverse and comminuted fractures which more often involved a considerable injury to the lateral expansions. The result of patients non operatively treated, was excellent or good in 99 per cent. After operative treatment the result was excellent or good in 79 per cent. The late results were equivalent after osteosynthesis and partial patellectomy, but worse after total excision of the patella performed only in selected cases with open fracture.

On the basis of a survey of the literature and on this investigation it has been possible to come to some conclusions and to give recommendations for the treatment of acute fracture of the patella.

Albee introduced the intraarticular arthrodesis of the hip in 1908. Until quite recently this method has maintained a prominent position in the surgical treatment of painful coxarthrosis (Rütti 1969). According to the literature the chief advantage of arthrodesis over other methods is that it gives permanent relief from pain and instability. The operation has therefore traditionally been considered well indicated for people doing heavy work or whose occupation involves much walking and/or standing.

The aim of the operation in bilateral hip disease has commonly been to achieve not only stability and freedom from pain in the more severely affected joint but at the same time to retard or arrest progress of the disease in the less affected hip. The leg on the fused side was thus intended to be used for main support (Watson-Jones 1956, Francillon 1957, Wiberg 1959, Herbert 1960, Mach 1964, Verheugen and Navarre 1964, Becker 1969).

However, a fairly extensive search of the literature failed to reveal adequate studies of the support pattern following arthrodesis of the hip or of the fate of the (unoperated) mobile hip compared with its preoperative condition in the two forms of coxarthrosis, the primary and secondary.

This investigation attempts such a study of 125 cases who had 2 to 22 years previously undergone arthrodesis because of unilateral or bilateral coxarthrosis. The investigation comprised a registration of the static support pattern, a comparative study of preoperative and follow up radiograms of the mobile hip and a clinical examination. The following parameters were studied:

- a) the extent to which the fused hip was used for static support
- b) the incidence, rate and degree of radiographic deterioration of the mobile hip
- c) the incidence and severity of pain in the mobile hip and the limiting effect of pain on daily activities and working capacity

Albee introduced the intraarticular arthrodesis of the hip in 1908. Until quite recently this method has maintained a prominent position in the surgical treatment of painful coxarthrosis (Rütt 1969). According to the literature the chief advantage of arthrodesis over other methods is that it gives permanent relief from pain and instability. The operation has therefore traditionally been considered well indicated for people doing heavy work or whose occupation involves much walking and/or standing.

The aim of the operation in bilateral hip disease has commonly been to achieve not only stability and freedom from pain in the more severely affected joint but at the same time to retard or arrest progress of the disease in the less affected hip. The leg on the fused side was thus intended to be used for main support (Watson-Jones 1936, Francillon 1957, Wiberg 1959, Herbert 1960, Mach 1964, Verheugen and Navarre 1964, Becker 1969).

However, a fairly extensive search of the literature failed to reveal adequate studies of the support pattern following arthrodesis of the hip or of the fate of the (unoperated) mobile hip compared with its preoperative condition in the two forms of coxarthrosis, the primary and secondary.

This investigation attempts such a study of 125 cases who had 2 to 22 years previously undergone arthrodesis because of unilateral or bilateral coxarthrosis. The investigation comprised a registration of the static support pattern, a comparative study of preoperative and follow-up radiograms of the mobile hip and a clinical examination. The following parameters were studied:

- a) the extent to which the fused hip was used for static support
- b) the incidence, rate and degree of radiographic deterioration of the mobile hip
- c) the incidence and severity of pain in the mobile hip and the limiting effect of pain on daily activities and working capacity

## A Classification of Coxarthrosis

On the basis of preoperative radiograms of the hips the cases were classified as unilateral or bilateral coxarthrosis. Radiographic signs of osteophytes, narrowed joint space or structural changes were used as criteria of coxarthrosis (Heripret Danielsson and Dymling 1964). Distinction between primary and secondary coxarthrosis was based on the history and radiographic appearance.

## B Material

The source material comprised 336 cases treated at the Orthopedic Departments of the Lund University Hospitals in Lund and Malmö. Arthrodesis because of coxarthrosis came into regular use in Lund in 1945 and in Malmö in 1952. All cases operated through 1965 were included in the source material. It consisted of 195 females and 141 males, a ratio of 1.3/1. The average age at operation was 55 years, the same for both sexes. Over half of the cases were 50 to 65 years old at operation (Fig. 1).

### 1 Basic Material

Hospital records of 9 cases were missing or incomplete. This reduced the number of cases to 327 (Basic Material) on which adequate data were available. From the records and radiographic descriptions of these cases it was found that at the time of operation 177 had unilateral and 150 bilateral coxarthrosis. The distribution between primary and secondary coxarthrosis was 191 and 136 cases respectively.

### 2 Selection of the Probands

Only cases filling the following requirements were accepted:

- a) the mobile hip must not have been rendered unfit for radiographic assessment by a high congenital dislocation or some intra-articular operation.

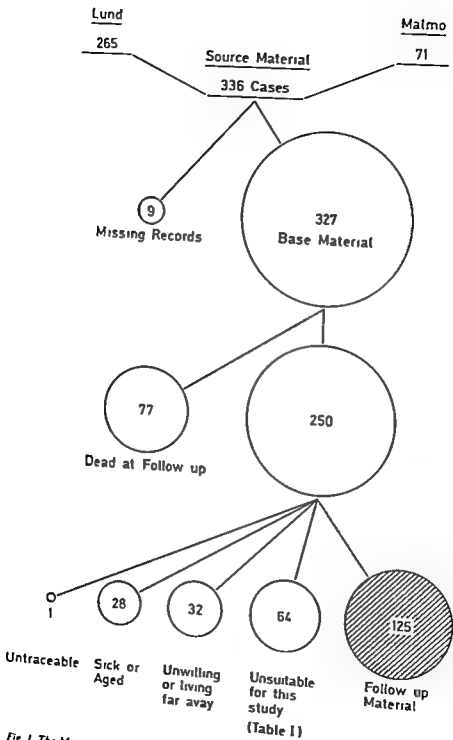

Fig 1 The Material

- b) radiographic and/or clinical signs of firm union in the operated hip,
- c) available preoperative radiograms of the mobile hip or adequate radiographic and clinical descriptions of the preoperative state
- d) availability of the case at the time of follow-up examination

Potential probands were contacted by letter and/or telephone. All those willing and able to participate were examined. In all 159 cases were examined but 34 of these failed to meet the above requirements (non-union 28, arthroplasty of mobile hip 4, high congenital dislocation of mobile hip 2). A further 30 were excluded because of similar findings in the records and radiograms (Table 1).

Table 1 Cases found unsuitable for follow-up

Cause	Number
<u>Mobile Hip</u>	
Arthroplasty or Resection	15
High Congenital Dislocation	3
<u>Operated Hip</u>	
Resection (Girdlestone)	4
Non-union	41
Femoral Amputation	1
Total	64

In 12 cases the radiograms obtained at follow-up were inconclusive: 1) lacking in definite radiographic evidence of solid union. All these hips were free from pain and clinically firmly united. Although osseous union may not always have been complete, all 12 cases were accepted as probands.

Of 16 cases in which preoperative radiograms of the mobile hip were not available, 10 were free from signs of arthrosis at follow-up. The remaining 6 had minimal changes: 1) only slightly reduced joint space and/or marginal osteophytes. The interval between the operation and follow-up of these 6 cases was 15 to 22 years. It was therefore considered reasonably certain that these hips had been

normal at the time of operation. These cases were accepted as probands.

Four cases with bilateral disease at the time of operation were accepted as probands despite unavailability of preoperative radiograms of the mobile hip. The hospital records of all 4 cases contained adequate descriptions of the original radiograms.

### 3 Description of Probands

Seventy seven of the 125 probands were females and 48 males a ratio of 1.6/1. At operation 75 probands had unilateral and 50 bilateral coxarthrosis and 61 had primary and 64 secondary coxarthrosis in the hip that was fused.

The distribution within the different subgroups of the material was largely the same in the Base Material as in the Follow-up Material (Fig. 2). The only appreciable difference was a relative loss of males with primary coxarthrosis and a corresponding gain of females with secondary coxarthrosis.

Of the 77 cases dead at follow-up 42 were males. Two thirds of the 77 cases had had primary coxarthrosis.

#### a Unilateral Coxarthrosis

Of the 75 cases operated for unilateral coxarthrosis 50 had secondary and 25 primary coxarthrosis. The diagnoses in the secondary cases are given in Table II. There were 53 females and 22 males.

## c Age at Operation

More than half of the probands were 50 to 65 years old at the time of operation The average age was 52 years and was the same in both sexes The average age of those with primary coxarthrosis was 8 years higher than of those with secondary coxarthrosis or 56 and 48 years respectively The youngest proband at operation was 17 years and the oldest 74 years

## II Age at Follow up

Over half of the probands were 60 to 75 years old The average age was 61 years (Fig 3) and was the same in both sexes The

average age of the probands with primary coxarthrosis, mainly bi- lateral was 66 years while the corresponding age of the probands with secondary coxarthrosis, mainly unilateral, was 57 years The youngest proband at follow-up was 19 years and the oldest 84 years

Fig 3 Age Distribution at Follow up

### ■ Follow-up Period

The interval between operation and the follow-up examination was 2 to 22 years For 102 of the probands it was at least 5 years The average interval was 10 years and was the same for females and males and for unilateral and bilateral coxarthrosis

### f Length of Hospitalization

Four probands were referred to their local hospitals a few days postoperatively for further convalescence The rest were discharged as soon as they could walk and manage at home usually with domestic help

Of the remaining probands, 109 operated upon once spent on the average 3.3 months (range 1-7 months) in hospital 9 operated upon twice 5.7 months (range 2.5-11 months) and the remaining 3 operated upon three or four times 8 months (range 4.5-10 months)

The above figures include only operations for securing fusion i.e. no osteotomies, extraction of nails or sequestrectomies etc

## I Follow up Procedure

The follow-up procedure was carried out from February 1968 to February 1969 and comprised a registration of the mode of static support radiographic and clinical examinations

The whole procedure took 2 5 3 hours As a rule the static support test was carried out first and was performed by an assistant at the Balance Laboratory of the Department of Otolaryngology in Lund Thereafter the radiographic examination was performed at the Department of Radiology Section II which serves the Orthopaedic Department The radiographic examination was followed immediately by the clinical examination which was always made by the author

## II Static Support Test

### a Purpose

The purpose of the test was to find out

- i) which leg was preferred under static conditions in unilateral and bilateral coxarthrosis
- ii) whether this support pattern was influenced by the position of the fused hip and/or discrepancy in relative leg length
- iii) the number of shifts of leg most loaded and to compare this with what may be considered normal in healthy individuals
- iiii) whether the probands were able to load both legs equally and whether the ipsilateral and contralateral leg could be used for supporting leg ( $> 60\%$  of body weight) alternately for a short period of time
- viii) the support pattern during Romberg's test and compare this with the preferred pattern in the first part of the test

Of further interest was a comparison of the opinion of the probands and the results of the test as regards which leg was generally loaded with more than half of body weight

### b Equipment

At the Balance Laboratory of the Otolaryngological Department certain equipment was used for registration of Romberg's test (Henriksson Johansson Olsson and Östlund 1967)

After slight modifications this equipment proved well suited for studying the pattern of static weight distribution. It consisted of a platform (109 x 90 cm height 21.5 cm) in two sections, enclosing two electric scales (Bofors Co. Sweden), working on strain gauge principles (Fig. 4). The scales, one for each foot, contained two strain gauges each. The platform and scales were movable, easily adjustable to individual requirements and indistinguishable from quite firm footing.

A voltage proportional to the weight on each scale was registered on an inkwriter (Mingograf) calibrated so that 100% of body weight gave identical amplitude. The equal deviation from the base line which represented even loading on both scales.

By recording the difference in voltage between the scales on one of the channels of the inkwriter (Channel 1) the difference in load on the scales was measured. On Channel 2 the algebraic values for deviations (deviations toward the right minus deviations toward the left or vice versa) were electrically integrated and recorded (Fig. 4).

### c Procedure

The static support test was developed by the author. The test lasted for exactly 20 minutes. With calibration and various delays the actual measuring time was often 5 to 10 minutes longer.

After adjusting the distance between the scales to the comfort of the proband, the scales were calibrated. The probands were not informed in advance of the various parts of the test. To begin with they were asked to stand in their habitual manner as when waiting for a bus or standing in a queue. All other instructions were given at appropriate intervals.

- i) Preferred mode of support was registered for two 5 minute periods, interrupted by 5 minutes of equal support on both legs (vide infra). This interruption had a dual purpose: first to find whether the probands returned to the same mode of support and then to find whether the frequency of shifts increased in the latter period.
- ii) During a 5 minute period the probands were asked to load both legs as equally as possible. They were routinely reminded of this about once every minute.
- iii) In direct continuation of the above 15 minutes the probands were instructed first to load the mobile leg for 2 minutes in a relaxed manner to relieve the fused leg and then vice versa by loading the fused leg.

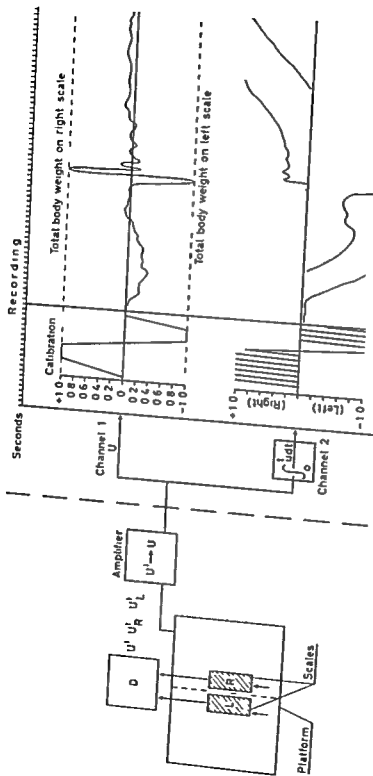

Fig 4 Recording of Static Support Pattern

After slight modifications this equipment proved well suited for studying the pattern of static weight distribution. It consisted of a platform (109 x 90 cm height 21.5 cm) in two sections enclosing two electric scales (Bofors Co - Sweden), working on strain gauge principles (Fig. 4). The scales, one for each foot, contained two strain gauges each. The platform and scales were movable, easily adjustable to individual requirements and indistinguishable from quite firm footing.

A voltage proportional to the weight on each scale was registered on an inkwriter (Mingograf) calibrated so that 100% of body weight gave identical amplitude, i.e. equal deviation from the base line which represented even loading on both scales.

By recording the difference in voltage between the scales on one of the channels of the inkwriter (Channel 1) the difference in load on the scales was measured. On Channel 2 the algebraic values for deviations (deviations toward the right minus deviations toward the left or vice versa) were electrically integrated and recorded (Fig. 4).

### c Procedure

The static support test was developed by the author. The test lasted for exactly 20 minutes. With calibration and various delays the actual measuring time was often 5 to 10 minutes longer.

After adjusting the distance between the scales to the comfort of the proband, the scales were calibrated. The probands were not informed in advance of the various parts of the test. To begin with they were asked to stand in their habitual manner as when waiting for a bus or standing in a queue. All other instructions were given at appropriate intervals.

- i) Preferred mode of support was registered for two 5 minute periods, interrupted by 5 minutes of equal support on both legs (vide infra). This interruption had a dual purpose: first to find whether the probands returned to the same mode of support and then to find whether the frequency of shifts increased in the latter period.
- ii) During a 5 minute period the probands were asked to load both legs as equally as possible. They were routinely reminded of this about once every minute.
- iii) In direct continuation of the above 15 minutes the probands were instructed: first to load the mobile leg for 2 minutes in a relaxed manner to relieve the fused leg, and then vice versa by loading the fused leg.

a line representing the pelvic horizontal (*vide infra*) and a line drawn along the inner contour of the proximal femoral shaft

Table IV    Assessment of Radiographic Severity

	Hyperdensity or cysts in caput and in acetabulum	2
	Grossly destroyed	3
Associated anomalies	None	0
	Double Floor	1

Radiograms of the lumbar spine and knees had not always been taken before the operation. Comparison with the radiograms obtained at follow up was therefore rarely possible but these radiograms demonstrated arthrotic changes in other adjoining joints

#### a Procedure

The hip joint was always fused in a varying degree of flexion. If abduction and adduction is determined radiographically with the central ray directed on the symphysis the flexed position will tend to increase the angle of abduction measured on the film and decrease that of adduction.

- 111) Finally, Romberg's test was carried out, the probands being instructed to stand with their eyes closed for as long as possible up to 1 minute

All stages of the test were done successively. This proved fairly strenuous for some of the probands. None of the probands expressed difficulty in assuming or maintaining their habitual standing position. Two probands were allowed to use a cane to keep their balance. Eleven probands were tested twice at 3 to 11 month intervals. No appreciable difference was found between the results of the two tests.

#### d Calculation

The tracings on Channel 1 (Fig. 4) represented the difference in loading of the two scales expressed as body weight (P). The tracings on Channel 2 represented the integrated loading difference expressed as body weight multiplied by time. The speed of integration was adjusted so that during calibration with total body weight on one scale the integrator was filled in one second, each stroke representing "1 body weight" per second (Fig. 4).

After each period of the test, the difference between the number of strokes on both sides of the base line was divided by the number of seconds in that period. The result gave a constant (k) by which the average loading on each of the two scales could be calculated from the expression  $P = \frac{1+k}{2}$  for the leg supporting the major part of body-weight and  $P = \frac{1-k}{2}$  for the other during the period.

To avoid repetition and misunderstanding it was found convenient to express average loading of the fused leg as a percentage of body-weight. Thus, if e.g. the average weight supported by the mobile leg during a certain period was 65% of bodyweight, it was expressed as 35% f 1 (fused leg).

### 3 Radiographic Examination

At follow-up all probands were subjected to radiographic examination of the pelvis, hips, lumbar spine and knees. The aims of the radiographic examination were primarily

- a) to assess radiographic signs of coxarthrosis as compared with those in preoperative radiograms. The severity of the changes was classified according to a numerical index (Table IV)
- b) to determine the degree of ab- and adduction of the fused hip by

The neutral angle according to Weinreich (1960) is that in which the midpoint of the hip knee and ankle joint are joined by a vertical line representing symmetrical weight distribution between both legs. In this mechanical midposition which is equivalent to a distance of about 18 cm between the midpoints of the two ankle joints the long axis of the femur is adducted toward the midline.

Lindahl (1965) chose a basic position with the feet together. In this position the neutral angle is formed by the pelvic horizontal and the leg (femur). The angle varies with the width of the pelvis and the leg length. This factor must be taken into account to secure uniform measurements. The neutral angle was calculated from the distance between the femoral heads on the radiograms and the length of the normal leg measured clinically.

1) Calculation of the Neutral Angle The neutral angle was calculated from the expression  $\cos \alpha = \frac{P}{2L}$  P denoting the distance between the femoral heads and L the length of the normal (mobile) leg.

When the angle of the fused hip as measured on the radiograms was smaller than the neutral angle the difference denoted the degree of adduction in the fused hip and conversely when greater the degree of abduction. This method was employed throughout the investigation. It was tested by calculating the neutral angle in 10 normal persons and was found to deviate by at most three degrees from the angle measured directly on their radiograms.

#### 4 Clinical Examination

The aim of the clinical examination was to assess and record

- a) the range of motion and degree of pain in the mobile hip
- b) the degree of flexion in the fused hip and
- c) the state of the lumbar spine and knees

Further notes were made of the probands' accounts of their working capacity.

The physical examination was carried out in a conventional manner (Method of Measuring and Recording American Academy of Orthopaedic Surgeons 1965).

Published methods for assessment of pain (Judet & Judet 1952, Shepard 1954, Stinchfield 1957, Danielsson 1964) use a numerical index from (0) 1 to (5) 6. In the author's opinion hip pain was best assessed by its restrictive effects on daily activities and work or sleep and by the use of analgesics rather than by noting starting

In most cases the angle formed by the fused leg and the table could be easily eliminated by extension (lordosis) of the lumbar spine. However, owing to stiffness of the back this was not always complete. This source of error was eliminated by the following procedure (focal distance 150 cm)

First Radiogram With the proband supine on AP projection was taken with vertical direction of the rays, centered immediately above the symphysis. Film size 30 x 40 cm covering the whole pelvis and upper part of both femoral shafts. A metal measuring scale was placed under the proband i.e. between him and a mattress covering the table.

Second Radiogram The floating table top was moved laterally about 10 cm to center the beam over the fused hip. Film size 30 x 40 cm, was placed longitudinally, covering the hip and at least 10 cm of the femoral shaft. The metal scale was in the same position as in the first radiogram.

Conventional frontal and lateral projections of the mobile hip, knees and lumbar spine were obtained.

#### b Measurement of the Frontal Position of the Fused Hip

The measurement was made as follows

On the first radiogram a reference line was drawn through the lower ranges of the sacro-iliac joints. On the second radiogram a line was drawn along the inner contour of the upper femoral shaft. This radiogram was then superimposed on the first using the metal scale as a landmark. The reference line of the first radiogram was then traced on the second. The angle thus formed by the two lines gave the frontal angle of the fused hip.

1) The Neutral Position In clinical practice the frontal position and motion in ab- and adduction have traditionally been measured from a zero position in which the anterior contour of the thigh forms a right angle with the superior-anterior iliac spines.

This position actually represents a considerable degree of abduction in the hip owing to the inclination of the femur toward the median plane. In the upright position it will correspond to an abduction of the hip of nearly 10 degrees from the standing position (Charnley 1953).

The neutral angle according to Weinreich (1960) is that in which the midpoint of the hip knee and ankle joint are joined by a vertical line representing symmetrical weight distribution between both legs. In this mechanical midposition which is equivalent to a distance of about 18 cm between the midpoints of the two ankle joints the long axis of the femur is adducted toward the midline.

Lindahl (1965) chose a basic position with the feet together. In this position the neutral angle is formed by the pelvic horizontal and the leg (femur). The angle varies with the width of the pelvis and the leg length. This factor must be taken into account to secure uniform measurements. The neutral angle was calculated from the distance between the femoral heads on the radiograms and the length of the normal leg measured clinically.

ii) Calculation of the Neutral Angle The neutral angle was calculated from the expression  $\cos \alpha = \frac{P}{2L}$  P denoting the distance between the femoral heads and L the length of the normal (mobile) leg.

When the angle of the fused hip as measured on the radiograms was smaller than the neutral angle the difference denoted the degree of adduction in the fused hip and conversely when greater the degree of abduction. This method was employed throughout the investigation. It was tested by calculating the neutral angle in 10 normal persons and was found to deviate by at most three degrees from the angle measured directly on their radiograms.

#### 4 Clinical Examination

The aim of the clinical examination was to assess and record

- a) the range of motion and degree of pain in the mobile hip
- b) the degree of flexion in the fused hip and
- c) the state of the lumbar spine and knees

Further notes were made of the probands' accounts of their working capacity.

The physical examination was carried out in a conventional manner (Method of Measuring and Recording American Academy of Orthopaedic Surgeons 1965).

Published methods for assessment of pain (Judet & Judet 1952, Stepard 1954, Stinchfield 1957, Danielsson 1964) use a numerical index from (0) 1 to (5) 6. In the author's opinion hip pain was best assessed by its restrictive effects on daily activities and work or sleep and by the use of analgesics, rather than by noting starting

pain pain when walking etc Assessment was therefore restricted to the following four grades

Grade 0 no pain

Grade 1 slight or occasional pain rarely interfering with work or daily activities often relieved by rest and seldom requiring analgesics ,

Grade 3 moderate pain that may periodically interfere with work or activities and requiring frequent use of analgesics

Grade 5 severe or disabling pain curbing activities and work disturbing sleep or so severe that the proband had been granted a disability pension

Functional capacity after the operation was assessed by grading some daily activities and working capacity The grading was based on Shepard s (1954) method but slightly shortened Thus e g limp and difficulty in putting on socks and shoes were omitted as these were natural consequences of a successful arthrodesis and were present in all cases (Table XX)

## 5 Statistical Methods<sup>1)</sup>

Only well known statistical techniques were used (Blom G 1969) mainly the chi-square test In a few cases the sign test and Student s t-test were applied

Statistical significance was described as follows

$P > 0.05$	= not significant
$0.05 > P > 0.01$	= almost significant
$0.01 > P > 0.001$	= significant
$0.001 > P$	= highly significant

## A Static Support Test

## 1 Preferred Mode of Support in Standing

a Support Pattern

Henriksson et al (1967) who used the same equipment as that used in this investigation (cf p 13) found that normal persons seemed to deviate on the average 6 - 77 of body weight in the lateral direction. Therefore deviations from the base line of up to 10% of body weight were in the present investigation taken to signify equal weight distribution on both legs and henceforth termed equal support (40° - 60° ± 1). Accordingly an average load of > 60% of body weight on either leg during this part (10 min) of the test was taken as a sign of a clear preference for the leg in question (supporting leg).

The support pattern obtained with the above differentiation is illustrated in Fig 5. There were two groups representing an average loading of > 60% of body weight on one leg and a middle group with equal loading on both. The mobile leg was used as a supporting leg three times as often as the fused leg.

Fig 5 Static Support Pattern Preferred Mode of Support during 10 Minutes

The difference in support pattern between the unilateral and bilateral cases is also illustrated in Fig 5. The main difference was that in two thirds of the bilateral cases both legs were loaded equally, whereas in over half of the unilateral cases there was a clear preference for the mobile leg.

One hundred and twelve of the probands showed the same support pattern in both 5 minute periods. In the 13 probands who did not, the mean value of both periods placed all but one within the group with equal support.

### Comments

The opinion of the probands as to which leg was generally loaded with more than half of body weight (main support) was compared to the results of the preferred support pattern. The base line (50% of body weight on each leg) divided the material in two parts (Fig 5) two thirds (84) loading the mobile leg with more than half of body weight and one third (41) the fused leg. Six probands had even loading on both legs. These were divided equally among the two groups. The result of the test bore a close resemblance to the opinion of the probands as 87 (70%) thought they generally loaded the mobile leg with more than half of body weight during standing, 29 (23%) the fused leg and 9 (7%) both legs equally.

The opinion of the probands regarding the leg mostly used for support during standing was in agreement with the results of the test in over 75% of the cases. Most of the 32 probands whose opinion differed from the results of the test displayed no clear preference for either leg (40% - 60% f 1).

Hohman (1962) studied the support pattern in 75 cases with hip arthrodesis by letting them stand on two scales for 15 minutes. He found that the fused leg was loaded in the following manner up to 1/4 of body weight 19%, 1/4 - 1/2 of b w 51% and over half of body weight 30%. The corresponding figures in the present material were up to 1/4 of b w 7%, 1/4 - 1/2 of b w 60% and over half of body weight 33%, and thus in good agreement with those given by Hohman. Further both investigations revealed that support by the fused leg and fairly equal support by both legs was more common than what is given in other reports based on clinical observations but without measuring devices (Table V).

Table V Preferred Mode of Support in Standing  
Earlier Studies compared with the Present

Author	Number of Cases	Support Pattern		
		Fused Leg	Mobile Leg	Both Legs

b Support Pattern in Relation to Frontal Position of Fused Hip

There was a difference in support pattern between probands with adduction and those with abduction of the fused hip. In the former the fused leg was more often used for main support than in the latter. Of 38 probands with adduction of the fused hip 16 used the fused leg for main support compared with 25 of the 87 probands with abduction.

Cases with from 5 degrees of adduction to 5 degrees of abduction in the fused hip were pooled and the group was called neutral (Table VI). There were 58 cases with neutral position 12 with adduction (range 6-12) and 55 cases with abduction of the fused hip (range 6-25). The distribution of the 41 cases which used the fused leg for main support within the adduction, neutral and abduction groups was such that they constituted about 1/2, 1/3 and 1/4 of the cases in each group. The relative proportions within the three groups of the 19 cases which used the fused leg as supporting leg (>60% of 1) was roughly 1/4, 1/5 and 1/18 respectively.

Loading of the fused leg thus seemed to be facilitated by the neutral or adducted position.

The difference in support pattern between the unilateral and bilateral cases is also illustrated in Fig 5 The main difference was that in two thirds of the bilateral cases both legs were loaded equally, whereas in over half of the unilateral cases there was a clear preference for the mobile leg

One hundred and twelve of the probands showed the same support pattern in both 5 minute periods In the 13 probands who did not, the mean value of both periods placed all but one within the group with equal support

#### Support Pattern in Relation to Frontal Position of Fused Hip

There was a difference in support pattern between probands with adduction and those with abduction of the fused hip. In the former the fused leg was more often used for main support than in the latter. Of 38 probands with adduction of the fused hip 16 used the fused leg for main support compared with 25 of the 87 probands with abduction.

Cases with from 5 degrees of adduction to 5 degrees of abduction in the fused hip were pooled and the group was called neutral (Table VI). There were 58 cases with neutral position: 12 with adduction (range 6-12) and 55 cases with abduction of the fused hip (range 6-25). The distribution of the 41 cases which used the fused leg for main support within the adduction, neutral and abduction groups was such that they constituted about 1/2, 1/3 and 1/4 of the cases in each group. The relative proportions within the three groups of the 19 cases which used the fused leg as supporting leg ( $> 60^\circ$  [1]) was roughly 1/4, 1/5 and 1/18 respectively.

Loading of the fused leg thus seemed to be facilitated by the neutral or adducted position.

The difference in support pattern between the unilateral and bilateral cases is also illustrated in Fig 5. The main difference was that in two thirds of the bilateral cases both legs were loaded equally, whereas in over half of the unilateral cases there was a clear preference for the mobile leg.

One hundred and twelve of the probands showed the same support pattern in both 5 minute periods. In the 13 probands who did not, the mean value of both periods placed all but one within the group with equal support.

### Comments

The opinion of the probands as to which leg was generally loaded with more than half of body weight (main support) was compared to the results of the preferred support pattern. The base line (50% of body weight on each leg) divided the material in two parts (Fig 5) two thirds (84) loading the mobile leg with more than half of body weight and one third (41) the fused leg. Six probands had even loading on both legs. These were divided equally among the two groups. The result of the test bore a close resemblance to the opinion of the probands as 87 (70%) thought they generally loaded the mobile leg with more than half of body weight during standing, 29 (23%) the fused leg and 9 (7%) both legs equally.

The opinion of the probands regarding the leg mostly used for support during standing was in agreement with the results of the test in over 75% of the cases. Most of the 32 probands whose opinion differed from the results of the test, displayed no clear preference for either leg (10% - 60% f 1).

Hohman (1962) studied the support pattern in 75 cases with hip arthrodesis by letting them stand on two scales for 15 minutes. He found that the fused leg was loaded in the following manner up to 1/4 of body weight 19%, 1/4 - 1/2 of b w 51% and over half of body weight 30%. The corresponding figures in the present material were up to 1/4 of b w 7%, 1/4 - 1/2 of b w 60% and over half of body weight 33%, and thus in good agreement with those given by Hohman. Further, both investigations revealed that support by the fused leg and fairly equal support by both legs was more common than what is given in other reports based on clinical observations but without measuring devices (Table V).

According to Seevald and Debrunner (1964) one of the reasons why most of their cases (Table V) loaded the mobile leg was excessive flexion in the fused hip. In the present material however large flexion angles did not seem to have any adverse effect on loading of the fused leg.

#### d Frequency of Shifting Leg of Main Support

The normal energy saving static posture requires that body weight can be shifted freely (cf p 31) from one leg to the other. The number of shifts during the static support test was shown by the tracings of the inkwriter (Fig. 4). In the following a shift means that more than half of body weight was shifted from one leg to the other for at least 15 seconds.

The frequency of shifting was found to vary considerably with the support pattern. Those showing preference for one leg shifted more often in the early 5 minute period whereas those with equal support displayed increase in the number of shifts in the latter half of the test period. Further the average total frequency of shifts was highest for those with equal support (Table VIII).

Table VIII Preferred Mode of Support in Standing versus Number of Shifts of Supporting Leg

Support Pattern	Number of Shifts		Total	Average Number of Shifts
	First 5 min Period	Second 5 min. Period		
<40% f 1	22	15	37 52	0 71
40%-60% f 1	69	86	155 54	2 9
>60% f 1	18	6	24 19	1 3
Total	109	107	216 125	1 7
Average Number of Shifts	0 9	0 9		

#### Comments

Smith (1953) observed 250 persons standing in bus queues and found that most of body weight was shifted among the legs on the average every 30 seconds. He found asymmetrical standing i.e. what he considered nearly the whole weight of the body supported by one leg is

Total	109	107	216.125	1.7
Average Number of Shifts	0.9	0.9		

## Comments

Smith (1953) observed 250 persons standing in bus queues and found that most of body weight was shifted among the legs on the average every 30 seconds. He found asymmetrical standing i.e. what he considered nearly the whole weight of the body supported by one leg to

be about four times as frequent as symmetrical standing

Hohman (1962) studied the preferred manner of support of 75 probands with arthrodesis of the hip in standing during 15 minutes. He found that during the first few minutes the body weight was frequently shifted from one leg to the other, as a rule followed by a certain stability with slow variation. A change of supporting leg was rarely noted thereafter.

*The remarkably small number of shifts during the static support test compared with observations in normal persons, may be an indication of the restrictive effect of the fusion in this respect. The lower frequency of shifts among those mainly loading one leg suggests that the support pattern was deeply rooted and uniform as shifts were less frequent in the second half of the test. Thus the two to threefold frequency of shifts among the probands who displayed equal support may be explained by the fact that they had more symptoms in the mobile hip and therefore were less comfortable in any position.* (Table IX)

#### e Support Pattern in Relation to Leg Length Discrepancy

One hundred and seven of the probands had a discrepancy in relative leg length: 101 shortening and 6 lengthening of the fused leg. In 18 cases no difference was found.

The distribution according to support pattern and frontal position of the fused hip of the 52 cases with 2 cm or more of uncompensated shortening of the fused leg during the static support test was largely the same as that of the material as a whole (Table VI). Thus 22 showed equal support and the rest preferred support by one leg (19 the mobile and 11 the fused leg). Still the adducted or neutral position and support by the fused leg were somewhat more common in the 52 cases than in the rest of the material.

Equal support was on the other hand less common among the 21 cases with 3 cm or more shortening. Fifteen of these had preferred support by one leg (9 the mobile and 6 the fused leg).

Of the 6 cases with relative lengthening of the fused leg from 1 to 4 cm (average, 2 cm) 3 had compensatory heel raises on the mobile side. Four had equal loading on both legs and 2 preferred the mobile leg.

Eighteen cases had no measurable discrepancy in leg length. Eight loaded both legs equally: 7 preferred the mobile and 3 the fused leg.

Table IX

Preferred Mode of Support in Standing versus  
Increase in Radiographic Index and Pain in Mobile Hip

Support Pattern	Increase in Radiogr Index											Total	Average Increase in Radiogr Index	Pain Index	Number

Thus the two to threefold frequency of shifts among the probands who displayed equal support, may be explained by the fact that they had more symptoms in the mobile hip and therefore were less comfortable in any position. (Table IX)

#### e Support Pattern in Relation to Leg Length Discrepancy

One hundred and seven of the probands had a discrepancy in relative leg length: 101 shortening and 6 lengthening of the fused leg. In 18 cases no difference was found.

The distribution according to support pattern and frontal position of the fused hip of the 52 cases with 2 cm or more of uncompensated shortening of the fused leg during the static support test was largely the same as that of the material as a whole (Table VI). Thus 22 showed equal support and the rest preferred support by one leg (19 the mobile and 11 the fused leg). Still the adducted or neutral position and support by the fused leg were somewhat more common in the 52 cases than in the rest of the material.

Equal support was on the other hand less common among the 21 cases with 3 cm or more shortening. Fifteen of these had preferred support by one leg (9 the mobile and 6 the fused leg).

Of the 6 cases with relative lengthening of the fused leg from 1 to 4 cm (average 2 cm) 3 had compensatory heel raises on the mobile side. Four had equal loading on both legs and 2 preferred the mobile leg.

Eighteen cases had no measureable discrepancy in leg length. Eight loaded both legs equally: 7 preferred the mobile and 3 the fused leg.

## 2 Instructed Modes of Support in Standing

### a Equal Support by Both Legs

Eighty nine (71%) of the probands managed equal support for a period of 5 minutes. Of the 36 probands who failed 24 retained their preference for loading the same leg as they had in the first part of the test 18 of them the mobile leg and 6 the fused leg. Of the remaining 12 probands 11 who in the first part of the static support test showed equal support had changed to support by one leg 7 by the mobile leg and 1 by the fused leg. Of the remaining 4 cases 3 had changed from support by the mobile leg to the fused and 1 vice versa.

#### Comments

It is difficult to explain why these 36 cases could not manage equal support for a leg length discrepancy extreme positions of the fused hip or changes in the mobile hip or other joints were not more common in this group than in the rest of the material.

### b Support by Fused Leg

One hundred and eleven (89%) of the probands could use the fused leg for support ( $\geq 60\%$  of b w ) during a period of 2 minutes. This invariably involved more or less leaning toward the fused side and forwards.

Fourteen probands could not load the fused leg to such an extent average  $54\%$  f l (range  $41\%$  -  $60\%$  f l ). Ten had preferred the mobile leg in the former part of the static support test. Their support pattern thus appeared to be confined to one mode. Possible contributory causes in 8 of the latter were as follows: 5 had a combined abduction of the fused hip and severe arthrosis of the mobile hip with little or no frontal motion and 3 had pain in the ipsilateral knee when standing for any length of time.

### c Support by the Mobile Leg

One hundred and sixteen (93%) of the probands could use the mobile leg for support for two minutes. Of the 9 probands who could not 5 had equal support in the first part of the static support test and 3 had preferred the fused leg. The remaining one of these 9 was the oldest proband in the material an 84 year old woman with pain in the mobile

## Comments

Relative shortening of the fused leg was slightly more common in the 41 cases with main support by the fused leg than in the rest of the material. Twenty of the 41 cases had an uncompensated shortening of 2 cm or more compared with 32 of the remaining 84.

Large, uncompensated shortenings ( $\geq 3$  cm) were most common among the 19 cases with preference for the fused leg. Thus, one third (6) of these compared with one sixth (9) of those preferring the mobile leg and only ninth (6) of those with equal support had such large shortening.

Many of the probands had been reluctant to use a heel raise to compensate shortening of the fused leg. Only 46 of the 101 cases used a heel raise more or less regularly. Such compensation was seldom used if the shortening was less than 3 cm, but even 13 of the 41 probands with a shortening of 3 cm or more never used one. Of the 46 probands using a heel raise, 9 used it only intermittently or during working hours.

Practically all of the probands with a shortening of 2 cm or more had been prescribed a heel raise after operation. However, half of them had stopped using it because they felt that the fused leg had become too long and was more "in the way", often causing them to stumble or fall.

### f Support Pattern versus Radiographic Deterioration and Pain

The incidence and amount of radiographic deterioration and pain in the mobile hip was largest among those of the probands who preferred equal support or support by the fused leg (Table IX). Roughly two thirds of the latter showed increase in radiographic severity compared with one third of those who preferred the mobile leg. The difference was significant. As regards pain, three fifths of the former and nearly half of the latter had pain in the mobile hip.

The degree of deterioration and pain was thus least among the 52 probands who preferred the mobile leg for support. This was in good agreement with the views of many of the probands who stated that as symptoms increased in the mobile hip, more of their body weights had been transferred to the fused side.

The mode of standing and the forces acting on the hip joint under normal and pathologic conditions have been investigated by a number of authors (Walsmsley 1933 Akerblom 1948 Felton and Wright 1949 Smith 1953 Schede 1956 Fürmaier 1959 Weinreich 1960 Denham 1959 Hohman 1962 Jonsson and Steen 1962 Casuccio 1964 Rydell 1966 Henriksson et al 1967) The consensus of opinion is that if the standing position is to be maintained for any length of time body weight is not supported equally by both legs. Instead the posture of at ease is adopted, i.e. the bulk of body weight resting on one leg with Trendelenburg's sign positive. In this posture the large joints of the weight bearing extremity hip and knee are stabilized in the extended position by the strong ligaments reinforcing their joint capsules. Muscle activity is then largely confined to the interplay of antagonists for keeping balance, further facilitated by the passive counterweight of the unloaded leg (Fig. 6 b). This is the energy saving standing posture adopted during longer periods in which body weight is alternately shifted from one leg to the other, whereas maintaining balance on both legs requires considerably more muscle activity. A requirement for adopting and maintaining the former posture is that the line of body weight must pass through the center of the supporting foot, dividing the body into two balanced halves. A necessary condition for this is that the line of body weight passes medially to the supporting hip joint, which in turn involves lateral translation of the pelvis toward the supporting side along with lowering of the pelvis toward the unloaded side. The only other way of supporting body weight mainly by one leg is that with Trendelenburg's sign negative, which involves elevation of the pelvis on the unloaded side, abduction of the supporting hip joint and lateral translation of the pelvis along with a lumbar scoliosis convex toward the same side (Fig. 6 c). The posture with Trendelenburg's sign negative implies a continuous muscular effort and is therefore not adopted for longer periods, in daily life only when walking.

After arthrodesis of the hip, standing on the fused leg can no longer be facilitated by translation of the pelvis toward the loaded side by adducting the supporting hip. There are two possible ways by which the arthrodesed person can load the operated side with more than half of his body weight. In order to establish balance he can either lean the upper part of the body toward the side of support (Fig. 6 d) or by

hip and suffering from vertigo, which might perhaps explain the inconclusive results of the test as, in this part she had 46% f 1 but 35% f 1 in the first part of the test Of the 9 probands 6 had severe changes in the mobile hip with little or no frontal motion and, with pain (5 cases)

#### d Romberg s Test

Finally, Romberg s test was carried out Most of the probands managed to stand with their eyes closed for about 35-40 seconds or more Ninety of the probands displayed the same support pattern as they did in the first part of the test

The support pattern was thus found to have almost the same features as that of the first part of the static support test The main difference was that equal support by both legs was slightly more common in this part Thus 22 probands who preferred one leg in the first part had changed to equal support whereas 9 probands with equal support in the first part had changed to support (<40% f 1 ) by the mobile leg and 1 to the fused leg Thus the final support pattern in Romberg s test was <40% f 1 = 45 40% - 60% f 1 = 66 and >60% f 1 = 14 probands

#### Comments

The results of the second part of the static support test showed that in general the probands were able to load whichever leg they chose when a conscious effort was made to do so However, a few probands did not seem to have much choice in this regard due to stiffness and/or pain in the mobile hip For many of the probands support by the fused leg for 2 minutes proved exceedingly fatiguing and many expressed relief when this part of the test was over

As a rule support by the mobile leg was obviously better tolerated even by many of those suffering from pain in the mobile hip An interesting feature of the final period of the static support test was that most of the probands resumed their preferred mode of support from the first part of the test This was interpreted as a further sign that the support pattern displayed was characteristic of the individual

equal support pattern. Thus incidence and degree of pain in the mobile hip was least in the 52 cases who showed preference for the mobile leg.

As regards frontal position, main support by the fused leg appeared to be facilitated by the neutral or adducted position of the fused leg.

In more than half of the 41 cases with main support by the fused leg a combination of the above factors occurred. On one hand there was relative shortening and neutral or adducted position of the fused hip and on the other hand pain and/or stiffness of the mobile hip.

Symptoms from the knees did not seem to have a decisive influence on the support pattern although an occasionally contributory role was probable. Seventy six probands had knee symptoms, mostly in the form of slight and/or occasional pain. In 52 of these radiographic signs of gonarthrosis were found at follow-up. Radiographic changes were more common and slightly more advanced on the fused side.

Of the 19 probands who used the fused leg for support, 15 had some pain in the knees: 10 in the ipsilateral knee (fused side), 1 in the contralateral and 4 in both. Of the 52 probands who used the mobile leg for support, 13 had knee symptoms: 4 in the ipsilateral (fused side) knee, 3 in the contralateral and 6 in both. Of the 54 probands with equal support, 48 had symptoms from the knees: 24 in the ipsilateral, 6 in the contralateral and 18 in both knees.

Pain or fatigue in the lumbar region was a common complaint during protracted standing and sitting. Such symptoms were reported by 75 probands, 32 of whom felt that this impaired their standing and walking capacity. Sixty three of the former and 28 of the latter had radiographic signs of lumbar spondylarthrosis.

A slight increase in the incidence of lumbar pain with the degree of flexion in the fused hip was noted. Thus one half (19) of the 38 probands with small degrees (10 - 29°) of flexion compared to three fourths (18) of the 26 with large flexion (40 - 50°) angles had back pain.

#### 4 Conclusions

The support pattern when standing in a free or preferred manner showed that after arthrodesis of the hip the fused extremity was seldom used as the supporting leg; it was intended to become. Eighty five percent of the probands either displayed equal support or prefer

forcibly lifting up the mobile side the whole (fused) coxofemoral region can be brought to rotate around the axis of the subtalar joints until the line of gravity coincides with the supporting foot (Fig 6 e) Both these postures require continuous muscular effort for keeping balance along with more or less compensatory scoliosis the dimensions of which is dependent largely on the degree of abduction of the fused hip

The results of the static support test were in agreement with the above considerations - Two thirds of the probands loaded the mobile leg with more than half of their body weight and 42% of the total number of probands used the mobile leg for support ( $> 60\%$  of b.w by choice whereas only 15% chose the fused leg for support. The question then arises in what respect the probands loading the fused leg differed from the rest. Naturally a number of factors may influence the choice of leg for support e.g. relative leg length position of the fused hip, state of the mobile hip and symptoms from other adjoining joints chiefly the back and knees

Those probands who mostly loaded the mobile leg were of the opinion that support by the mobile leg was more comfortable whereas main support by the fused leg was more tiring both generally and for the back. More seldom the fused leg was spared owing to the feeling that it was still the sick one and had to be protected. This impression seemed real for a few probands and may have been a factor the importance of which is hard to estimate. A few probands reported that they avoided loading the fused leg in public as they felt their buttocks protruded too markedly

The probands who mostly loaded the fused leg gave entirely different reasons. Most of them thought the mobile leg had become too long after the operation. Those with large relative shortening of the fused leg were more or less compelled to stand with most of body weight on one leg or the other and some of these probands preferred standing on the fused leg than on the mobile leg, with the fused one hardly reaching the ground. This was in agreement with the results of the test as a large, relative shortening of the fused leg appeared to induce support by one leg

Many of the probands in whom the mobile hip had become painful in the interval between the operation and the follow-up examination reported that they had always used the mobile leg for support until it had become painful. Only then had they begun to shift more of body weight over to the fused side. This applied to many of the probands with an

ence for loading the mobile leg. The support pattern registered by Hohman (1962) in 75 hip arthrodesed subjects showed similar results (cf p 22).

Not before the mobile hip had become painful or more painful than preoperatively had more of body weight been shifted to the fused side by a conscious effort. This was borne out both by the probands' accounts and by the significantly higher incidence and degree of changes and pain in the mobile hip in those probands who displayed equal support and support by the fused leg.

Loading on the fused leg appeared to be facilitated by the neutral or adducted position of the fused hip and by shortening of the fused leg. On the other hand, the degree of flexion of the fused hip was not found to affect the support pattern.

The support pattern was very uniform in different parts of the test and shifts were markedly scarce compared with what may be considered usual in normal subjects.

In view of the results of the test and the opinion of the probands it was concluded that the alleged supporting role of the fused leg has not been based on factual evidence.

## B Radiographic Examination

### 1 Arthrotic Deterioration of Mobile Hip

#### a With Regard to Radiographic Appearance at Operation

1 Unilateral Coxarthrosis Of the 75 cases without signs of arthrosis of the mobile hip at operation 31 had developed such signs by the time of follow-up (Table IV) The average radiographic severity of the 31 hips was 1.9 index points (range 1-6) (Table X) Of these 31 cases 16 showed only signs of incipient arthrosis In 8 of the latter fused because of secondary arthrosis progress consisted of an osteophyte on one pole The remaining 8 fused because of primary arthrosis showed either narrowing of the joint space or structural changes In the remaining 15 cases reduction of the joint space was the most common finding in both types of arthrosis (9 secondary and 6 primary)

In unilateral coxarthrosis the course of the mobile hip was usually favourable for the first few years Radiographic changes were mostly mild and although the incidence of arthrosis rose sharply after 5 years two thirds of the hips showed no signs of arthrosis up to 10 years after operation Of the remaining third reviewed after a longer interval half the number deteriorated (Table XI)

11 Bilateral Coxarthrosis Of the 50 cases with a varying degree of arthrosis of the mobile hip at the time of operation the average radiographic severity had increased by 3.1 index points (range 1-8) in 37 (Table XI)

radiographic changes. Thirty of the present 75 unilateral cases were reviewed 2 to 7 years after operation by which time degenerative changes had appeared in 7. Demigneux et al (1968) found an incidence of 14 of 92 unilateral cases reviewed 5 to 15 years after operation. The etiological composition was not stated. In the present material 18 of the 42 unilateral cases reviewed 5 to 15 years after operation had developed signs of arthrosis. In a series of 75 cases Hauge (1963) found incipient arthrosis in only 6 of the mobile hips examined 5 to 20 years after the operation. All but 4 had been fused for tuberculosis or some unspecific inflammation. Mean age at follow-up was 36 years. The lower incidence in the last two series compared with the present was probably due primarily to the higher percentage of secondary coxarthrosis and the lower average age in these two series.

Demigneux et al (1968) reviewed 41 cases fused 5 to 15 years previously because of bilateral coxarthrosis. At follow-up 24 had been subjected to mobilizing operations of the other hip (5 before the fusion). Of the remaining cases 14 had showed signs of mild arthrosis of the mobile hip at operation. At the review all were found to have deteriorated and 11 of them considerably. Merle d'Aubigne, Ramadier, Postel, Mozas and Vaillant (1964) reviewed 59 cases arthrodesed  $2\frac{1}{2}$  12 years previously for bilateral coxarthrosis. Deterioration of the mobile hip had occurred in 31 cases, 8 of which had been operated upon. Of the present 39 bilateral cases with up to 12 years in follow-up time 19 had deteriorated.

#### b. Type of Arthrosis of Fused Hip

Of the 75 unilateral cases 50 hips had been operated for secondary and 25 for primary coxarthrosis. Of the 31 probands who developed signs of arthrosis 17 had had secondary and 14 primary arthrosis in the fused hip.

The average radiographic deterioration of the mobile hip was 0.7 in the 50 secondary and 1.0 index points in the 25 primary cases. Of the 50 secondary cases deterioration of the mobile hip was greatest in the 21 cases operated for arthrotic changes secondary to some developmental disturbance, mild in the 18 cases fused because of late effects of coxitis and absent in the 11 cases fused because of late complications of fracture of the femoral neck (Table XIII A 1).

Of the 50 bilateral cases 36 had primary and 14 secondary arthrosis of the fused hip at operation. In 28 of the former and in 9 of

Forty one of the bilateral cases had had up to 5 in initial radiographic index. Thirty two of these showed progress. Average incidence and amount of radiographic progress was roughly the same in these five index groups. i.e. four fifths of the probands and over 3 index points increase in each. Of the remaining 9 probands with an initial index of 6 or more 5 had progressed on the average 1.8 points.

As in unilateral coxarthrosis, joint space reduction was the commonest sign of progress. Structural changes occurred two and a half times as often as in unilateral coxarthrosis. Eleven of these 37 hips showed only one sign of progress. In 4 of these a new osteophyte had formed while in the 7 others the joint space had become narrowed. In the remaining 26 cases, joint space reduction was also the most common sign (Table X).

The radiographic deterioration of the mobile hip appeared sooner and progressed more rapidly in bilateral than in unilateral coxarthrosis (Table XI). Only one third of these cases had remained stationary for up to 10 years after operation and only one fifth for a still longer interval. The radiographic deterioration was also more severe in the bilateral cases (Figs 10-12 p 74-79).

The difference in incidence of radiographic signs of arthrotic deterioration between the unilateral and bilateral cases was significant.

Average degree of arthrotic deterioration in the 75 unilateral cases was 0.8 and in the 50 bilateral cases 2.3 index points. The difference was significant (Table XII).

Table XII Radiographic Deterioration in  
Unilateral and Bilateral Coxarthrosis

	Increase in Radiographic Severity			
	0	1	2	≥3
Unilateral Coxarthrosis	44	16	9	6
Bilateral Coxarthrosis	13	11	8	18
Total	57	27	17	24 = 125

#### Comments

Hohman (1962) reviewed 75 cases operated upon 1 to 7 years previously because of primary or secondary coxarthrosis. Of the hips free from changes at operation he found that one fourth had developed

radiographic changes Thirty of the present 75 unilateral cases were reviewed 3 to 7 years after operation by which time degenerative changes had appeared in 7 Demigneux et al (1968) found an incidence of 14 of 92 unilateral cases reviewed 5 to 15 years after operation The etiological composition was not stated In the present material 18 of the 42 unilateral cases reviewed 5 to 15 years after operation had developed signs of arthrosis In a series of 75 cases Haug (1963) found incipient arthrosis in only 6 of the mobile hips examined 5 to 20 years after the operation All but 4 had been fused for tuberculosis or some unspecific inflammation Mean age at follow-up was 36 years The lower incidence in the last two series compared with the present was probably due primarily to the higher percentage of secondary coxarthrosis and the lower average age in these two series

Demigneux et al (1968) reviewed 41 cases fused 5 to 15 years previously because of bilateral coxarthrosis At follow-up 24 had been subjected to mobilizing operations of the other hip (5 before the fusion) Of the remaining cases 14 had showed signs of mild arthrosis of the mobile hip at operation At the review all were found to have deteriorated and 11 of them considerably Merle d'Aubigne, Pamadier, Postel, Mozas and Vaillant (1964) reviewed 59 cases arthrodesed 2 1/2 to 12 years previously for bilateral coxarthrosis Deterioration of the mobile hip had occurred in 31 cases 8 of which had been operated upon Of the present 39 bilateral cases with up to 12 years in follow up time 19 had deteriorated

#### b Type of Arthrosis of Fused Hip

Of the 75 unilateral cases 50 hips had been operated for secondary and 25 for primary coxarthrosis Of the 31 probands who developed signs of arthrosis 17 had had secondary and 14 primary arthrosis in the fused hip

The average radiographic deterioration of the mobile hip was 0.7 in the 50 secondary and 1.0 index points in the 25 primary cases Of the 50 secondary cases deterioration of the mobile hip was greatest in the 21 cases operated for arthrotic changes secondary to some developmental disturbance mild in the 18 cases fused because of late effects of coxitis and absent in the 11 cases fused because of late complications of fracture of the femoral neck (Table XIII A B)

Of the 50 bilateral cases 36 had primary and 14 secondary arthrosis of the fused hip at operation In 28 of the former and in 9 of

#### Comments

Danielsson (1964) reviewed 91 unoperated cases (121 hips) from 8 to 12 years (average 11 years) after clinical and radiographic diagnosis of coxarthrosis. The aim was to assess the prognosis of coxarthrosis and to provide a standard of comparison for operated cases. Radiographic changes were evaluated by comparison of initial and follow up radiograms according to the scheme used in the present investigation (Table IV). All 121 hips had structural and/or joint space changes at the time of diagnosis. The two materials were well comparable as regards number of hips, age (cf p. 48) and the average duration of the interval. Still, in the present material, 10 of the bilateral cases had been reviewed after more than 12 years. On the other hand, 85% of Danielsson's series had primary coxarthrosis against 50% of the present material.

Danielsson found that radiographic changes usually progressed (average 1.4 index points) and that primary coxarthrosis progressed radiographically more than secondary ( $1.7 \pm 0.13$  versus  $0.7 \pm 0.13$ ).

These figures, when compared with radiographic progress in all the primary (61) and secondary (64) cases in the present material, were found to be almost identical (1.9 versus 0.8 index points).

As all the hips in Danielsson's series had structural and/or joint space changes at the outset, comparison with the bilateral cases was of even greater interest. Of the 50 bilateral cases of the present material, the primary also progressed radiographically more than the secondary cases.

#### Comments

Danielsson (1964) reviewed 91 unoperated cases (121 hips) from 8 to 12 years (average 11 years) after clinical and radiographic diagnosis of coxarthrosis. The aim was to assess the prognosis of coxarthrosis and to provide a standard of comparison for operated cases. Radiographic changes were evaluated by comparison of initial and follow-up radiograms according to the scheme used in the present investigation (Table IV). All 121 hips had structural and/or joint space changes at the time of diagnosis. The two materials were well comparable as regards number of hips, age (cf p. 48) and the average duration of the interval. Still, in the present material, 10 of the bilateral cases had been reviewed after more than 12 years. On the other hand, 85% of Danielsson's series had primary coxarthrosis against 50% of the present material.

Danielsson found that radiographic changes usually progressed (average 1.4 index points) and that primary coxarthrosis progressed radiographically more than secondary (1.7  $\pm$  0.13 versus 0.7  $\pm$  0.13).

These figures, when compared with radiographic progress in all the primary (61) and secondary (64) cases in the present material, were found to be almost identical (1.9 versus 0.8 index points).

As all the hips in Danielsson's series had structural and/or joint space changes at the outset, comparison with the bilateral cases was of even greater interest. Of the 50 bilateral cases of the present material, the primary also progressed radiographically more than the secondary cases.

Of Danielssons s material one third showed no progression and in 8 hips signs of regression were observed Of the 50 bilateral cases of the present material one fourth showed no signs of progression but in no instance were signs of regression observed

The difference in radiographic deterioration of the mobile hip in the present 36 bilateral primary cases ( $2.6 \pm 0.12$ ) and Danielsson s 104 hips ( $1.7 \pm 0.13$ ) followed up on the average 11 years after a diagnosis of primary coxarthrosis had been made was significant

### c Interval Between Operation and Review

The interval was on the average the same for primary and secondary cases (10 years)

In unilateral coxarthrosis the average interval was over 3 years longer for the cases in which degenerative signs had appeared (Fig 7) Of the 43 cases where the interval was less than 10 years 14 displayed signs of deterioration compared with 17 of the 32 reviewed after a longer interval (Table XI)

Fig 7 Incidence and Degree of Radiographic Deterioration and Pain

Of the 75 unilateral cases 19 were reviewed after 15 to 22 years. Eleven of these showed an increase in radiographic severity from 1 to 6 points (average 2.1 index points) whereas 8 had remained stationary.

In bilateral coxarthrosis the cases with radiographic signs of progression had 3 years longer average interval than in the remaining 13 stationary cases (Fig. 7). Of 31 cases reviewed after periods up to 10 years 20 had deteriorated compared with 17 of the 19 reviewed after a long interval.

Only 4 of the bilateral cases had been reviewed after 15 to 22 years. All 4 showed heavy radiographic progress, average 5.2 points (range 5-8). Of the 13 cases who had not progressed the interval was less than 5 years in 6, between 5 and 10 years in 4 and 10 to 15 years in 3. The average for all 13 cases was 6.4 years.

#### Comments

In the unilateral cases the incidence of radiographic changes appeared to have increased more than their severity, while in the bilateral cases radiographic severity had increased steadily with time (Table XII).

Hohman in his series (cf p. 38) found an incidence of 10% at review from 1 to 2 years and 45% after 6 years or more. The incidence in the present material was 10 of 35 cases reviewed after 2 to 6 years and 58 of 90 cases reviewed after a longer period.

#### d. Frontal Position of Fused Hip

Eighty-seven (70%) of the probands had various degrees of abduction (>5°) from the neutral angle. The average degree and incidence of radiographic deterioration was slightly higher in the abducted position than in adduction or the neutral position (Table XV) but the difference was not statistically significant. The ratio of unilateral and bilateral cases in the three position groups was adduction 1/4/1, neutral 1/5/1 and abduction 1/5/1. Thus the same proportion in all three groups.

Of Danielssons s material one third showed no progression and in 8 hips signs of regression were observed Of the 50 bilateral cases of the present material one fourth showed no signs of progression but in no instance were signs of regression observed

The difference in radiographic deterioration of the mobile hip in the present 36 bilateral, primary cases ( $2.6 \pm 0.12$ ) and Danielsson s 104 hips ( $1.7 \pm 0.13$ ), followed up on the average 11 years after diagnosis of primary coxarthrosis had been made, was significant

### c Interval Between Operation and Review

The interval was on the average the same for primary and secondary cases (10 years)

In unilateral coxarthrosis the average interval was over 3 years longer for the cases in which degenerative signs had appeared (Fig 7) Of the 43 cases where the interval was less than 10 years 14 displayed signs of deterioration compared with 17 of the 32 reviewed after a longer interval (Table XI)

Fig 7 Incidence and Degree of Radiographic Deterioration and Pain

were observed in only 5 of the 24 probands reviewed up to 5 years after the operation. The fact that half of the unilateral and four fifths of the bilateral cases were found to have deteriorated by the time of review more than 5 years after operation and that the radiographic deterioration was more severe than in a comparable unoperated series (Danielsson 1964) and the absence of radiographic signs of regression did not suggest unburdening of the mobile hip.

Training the arthrodesed subject to load the fused leg has been suggested by authors who at review had found that many of their cases had developed arthrosis and/or pain in the mobile hip (Leger 1956, Hohman 1962, Mach 1964, Demigneux 1967). It can hardly be expected however that such a measure would permanently affect their standing habits. Standing is largely an unconscious effort as long as it does not incur discomfort or pain. With easy energy saving standing restricted to one side the arthrodesed subject will as a rule automatically exploit the pain-free mobile leg for this purpose. Furthermore, biological factors and the forces acting on the joint during gait, are bound to be more important for the fate of the mobile hip than static strain.

The compensatory demands on the mobile hip during walking are well documented (Steindler 1955, Seevald and Debrunner 1964, Casuccio 1964, Ducroquet 1965). The only way the fused leg can be swung forward is by way of the pelvis with the mobile hip as a pivot. This occurs during the stance phase of the mobile leg when the joint is being loaded with at least twice the body weight as the pelvis tilts and rotates around the femoral head. It is reasonable to expect that such compensatory exertion hastens the degeneration of any joint not biologically fit and congruent. It may be argued that the stiffness of the fused hip before the operation had placed similar demands on the mobile hip. But as a successful arthrodesis leads to a more active life the compensatory strain on the mobile hip will still be increased.

Other mechanical factors of probable importance for the fate of the mobile hip were: a) loss of suppleness of the gait as the remaining normal segments of the extremity can only partially compensate for the loss of the hip joint, pelvic tilt and rotation being important factors in decreasing the vertical displacement of the center of gravity of the body (Saunders, Inman and Eberhart 1953); b) reduction of the contact area in the mobile hip due to the commonly occurring inclination of the pelvis toward the fused side (Pagani, Morosini and Buratti 1967); and c) walk way studies have shown that the stance

## Comments

The abducted position of the fused hip was for a long time recommended to compensate for shortening of the leg. The rationale was that when such shortening was marked this source of compensation could be utilized for obviating unsightly aids for providing better feeling of contact with the ground ("Bodengefühl", Macháček 1956) and facilitate walking and standing without shoes.

The adverse effects of marked abductions have since been well recognized however and corrective osteotomies have not infrequently been reported (Hauge 1963). In the present material 3 such late osteotomies had been performed. The abducted position of the hip renders the gait awkward and requires circumduction of the fused leg in the swing phase and an increased strain is thrown on the back and the mobile hip during walking and standing with time entailing a risk of degenerative changes with symptoms (Furmaier 1959, Hohman 1962, Seevald and Debrunner 1964 and Demigneux, Rainaut and Cedart 1968).

The fact that radiographic deterioration even though only slight was largest in the abducted position suggests that this may have been a contributory factor.

## ■ Discussion

Radiographic signs of arthrotic deterioration of the mobile hip

were observed in only 5 of the 24 probands reviewed up to 5 years after the operation. The fact that half of the unilateral and four fifths of the bilateral cases were found to have deteriorated by the time of review more than 5 years after operation and that the radiographic deterioration was more severe than in a comparable unoperated series (Danielsson 1964) and the absence of radiographic signs of regression did not suggest unburdening of the mobile hip.

Training the arthrodesed subject to load the fused leg has been suggested by authors who at review had found that many of their cases had developed arthrosis and/or pain in the mobile hip (Leger 1956, Hohman 1962, Mach 1964, Demigneux 1967). It can hardly be expected however that such a measure would permanently affect their standing habits. Standing is largely an unconscious effort as long as it does not incur discomfort or pain. With easy energy saving standing restricted to one side the arthrodesed subject will as a rule automatically exploit the pain free mobile leg for this purpose. Furthermore biological factors and the forces acting on the joint during gait are bound to be more important for the fate of the mobile hip than static strain.

The compensatory demands on the mobile hip during walking are well documented (Steindler 1955, Seevald and Debrunner 1964, Casuccio 1964, Ducroquet 1965). The only way the fused leg can be swung forward is by way of the pelvis with the mobile hip as a pivot. This occurs during the stance phase of the mobile leg when the joint is being loaded with at least twice the body weight as the pelvis tilts and rotates around the femoral head. It is reasonable to expect that such compensatory exertion hastens the degeneration of any joint not biologically fit and congruent. It may be argued that the stiffness of the fused hip before the operation had placed similar demands on the mobile hip. But as a successful arthrodesis leads to a more active life the compensatory strain on the mobile hip will still be increased.

Other mechanical factors of probable importance for the fate of the mobile hip were: a) loss of suppleness of the gait as the remaining normal segments of the extremity can only partially compensate for the loss of the hip joint, pelvic tilt and rotation being important factors in decreasing the vertical displacement of the center of gravity of the body (Saunders, Inman and Eberhart 1953); b) reduction of the contact area in the mobile hip due to the commonly occurring inclination of the pelvis toward the fused side (Pagani, Morosini and Buratti 1967) and c) walk way studies have shown that the stance

phase on the fused side is diminished and prolonged on the mobile side (Seevald and Debrunner 1964) or on the "good side" in limping (Rydell 1966)

Other factors of possible importance were age at operation (within the etiological groups), sex, body weight and occupation. No appreciable influence of these factors could be discerned.

### 3 Conclusions

Incidence of radiographic deterioration of the mobile hip in the present material was similar to that found in comparable published series. The severity of radiographic deterioration in the bilateral cases was however significantly higher than in Danielsson's series of unoperated cases with the same average follow-up interval.

Arthrodesis of the hip was generally well tolerated by the contralateral hip provided the latter was free from changes at the outset and the susceptibility associated with the primary form of coxarthrosis.

The professed relief of the mobile hip when slightly or moderately affected was not sustained by the findings of the present investigation as with time the majority of these cases showed heavy increase in radiographic severity. The high rate of deterioration in bilateral coxarthrosis particularly the primary form strongly indicated that the fate of the mobile hip was dependent primarily on biological factors, i.e. its ability to withstand the mechanical surcharge thrown upon it. On the other hand the fate of the hip was not found to vary appreciably with such factors as sex, occupation or body weight.

It was concluded that the increase in radiographic severity in the present material compared with that of Danielsson's series refutes the hypothesis that arthrodesis results in mechanical relief of the mobile hip.

## 1 Pain in Mobile Hip

a Incidence

Sixty eight probands had pain in the mobile hip at follow-up (not to be confused with the 68 probands with arthrotic deterioration) Twenty one had had pain also before the operation Of the latter 10 had become worse 8 were unchanged and 3 had less pain than before Thus half of the probands had either developed pain or become worse The incidence of pain was significantly higher in the bilateral cases (Fig 7)

b Severity

At follow-up 35 probands had mild 21 moderate and 12 severe pain in the mobile hip (cf p 19) In two thirds of the painful hips radiographic severity had increased Degree of pain was significantly higher in these than in the remaining third with no increase (Fig 7) The average increase in radiographic severity was three times as large in the 33 hips with moderate or severe pain as in the 35 hips with mild pain

Of 43 overweight probands 21 had pain in the mobile hip Average severity of pain in these was the same (2.4 index points) as in the remaining 47 hips

c Relation to Range of Motion

Thirty-one of the mobile hips had less than 90 degrees of flexion and all but one of these had a flexion contracture Twenty-eight of these had shown radiographic changes at operation and 23 had since progressed

In all 35 probands had a flexion contracture in the mobile hip average 21 degrees (range 10-65) Thirty of these hips had shown changes at operation Twenty nine of the 35 probands had pain in the mobile hip with an average score of 2.8 index points

## Comments

Degel (1957) reviewed 115 arthrodesed cases from 3 to 8 years after operation In thirty nine (34%) the mobile hip had become pain-

ful or worse, it was unchanged in 61 and had become painless or better in 10

Of 75 cases subjected to arthrodesis Hohman (1962) found that the mobile hip had become painful or worse within 1-7 years in 37%

In the present material the incidence found at review within 10 years of the operation was the same as in the above two series namely 27 of 74 cases (average 2.6 index points) The corresponding figures for those examined after a longer period were 30 of 51 (average 2.3 points)

In his unoperated series, Danielsson (cf p. 41) found no relation between pain and etiology of the disease or sex. Two thirds of the hips in his series had become less painful during the follow-up period. In contrast, in half of the present material the mobile hip had become painful or worse (Table XVI)

Table XVI Incidence of Pain in the Present Material compared with Danielsson's Series (1964)

Degree of Pain	Danielsson (1964)			The Present Material		
	Male	Female	Total	Male	Female	Total
Developed Pain (or More Severe)	10	10	20	19	38	57
Unchanged	3	11	14	2	6	8
Less Severe	28	42	70	2	1	3
Always Painless	11	4	15	25	32	57
Total	52	67	119	48	77	125

At the time of diagnosis all the hips included in Danielsson's series had structural and/or joint space changes. For comparison 27 of the present 43 hips with such changes at operation had become painful or worse. The average age in Danielsson's series was 10 years higher in primary and 6 years higher in secondary coxarthrosis. This may have played some role as the amount of activity and work are likely to be less in the higher age groups.

Danielsson also studied the correlation between the severity of pain and contractures in various planes in 123 hips. He found that this correlation was strongest for flexion contracture. In the present material two thirds of the moderately or severely painful hips were found among the 35 with flexion contractures.

## 2 Working Capacity

At the time of operation 12 probands already had a pension 8 because of age and 4 because of disability. In the remaining 113 cases one of the chief goals of the operation was to restore working capacity. Of the 113 cases 21 were granted an old age (5) or disability (16) pension within 3 years after operation and never resumed working. Of the 92 cases who resumed work 56 were females and 36 males.

Return to the same type of work as before operation was more common among those who had light occupations than among those with 'moderate' or 'heavy' work (Table XVII). Two thirds of those who returned to their former occupation had been operated upon for unilateral coxarthrosis (Table XVIII).

Table XVIII Working Capacity After Operation

Working Capacity After Operation	Unilateral Cases		Bilateral Cases		Total
	Primary	Secondary	Primary	Secondary	
<u>Resumed working after op.</u>

	3	3	4	2	12 (9%)
<b>Total</b>	<b>25</b>	<b>50</b>	<b>36</b>	<b>14</b>	<b>125 (100%)</b>

Of the 113 cases 69 had unilateral and 44 bilateral coxarthrosis at the time of operation. Of the former 61 returned to some form of work against 31 of the latter.

The interval between operation and resumption of work ranged from 3 months to 2 1/2 years average 11.5 months. The average interval did not vary with category of work. It was 11.8 months in the 61 unilateral cases and 10.8 months in the 31 bilateral cases. It was on the average 10.4 months for males and 12.2 months for females (fig. 8).

*Fig 8 Interval Between Arthrodesis and Resumption of Work in 92 Cases*

Sixty four probands were pensioners by the time of the review. Thirty-one were receiving an old age pension and 33 a disability pension.

Of the 31 probands who were receiving an old age pension, 8 had been pensioners already before the operation. 5 within 3 years of the operation and had not resumed work and the remaining 18 had reached retirement age after having worked from 2 to 18 years (average 6.4 years) after the operation. Of the 31 probands, 22 had been operated upon because of primary coxarthrosis (Table XIX).

Of the 33 probands who were granted a disability pension, 4 had been pensioned off before the operation. 16 within 3 years of operation and had not resumed work and a further 13 after having worked for 1 to 20 years (average 6.4 years) after operation. Of the 33 probands, 23 had been operated for primary coxarthrosis (Table XIX).

Of the 61 probands still working at the time of the review, 46 were still engaged in the same occupation as before operation (Heavy 5, Moderate 13, Light 15 and Slight 13) whereas 15 had taken up lighter work. Six of the 61 probands were receiving a partial disability pension. Over half of these 61 probands had been operated upon be-

	12		21		18		61	

cause of unilateral secondary coxarthrosis (Table XIX)

In primary coxarthrosis the most common reason for a disability pension was pain and/or stiffness of the mobile hip. Seventeen of the 23 primary cases had been granted a disability pension for this reason. Five of the 10 secondary cases had been granted a disability pension because of pain and/or stiffness of the mobile hip. Common associated causes in both categories were obesity, cardiac trouble, a protracted postoperative course, sometimes with reoperations, symptoms referable to other joints (back and knees) and mental depression. In some cases difficulties in finding suitable work was probably a contributory factor.

### Comments

Working capacity is at least temporarily frequently improved or restored after arthrodesis of the hip. The frequency with which this occurs depends on a number of factors - such as age, general health, type of work etc. (Karlen 1944, Mayr 1954 and Acchiapatti 1962).

In the present material the chief difference in this respect was found between probands operated for secondary and primary coxarthrosis. Working capacity was improved more often and was more lasting among the former. Disability pension had since the operation been granted to 8 (12%) of the former and 21 (34%) of the latter.

### 3. Restriction of Function

By assessing and grading some important daily activities the degree of restriction of function in different parts of the series was compared (Table XX).

Walking Distance The probands' assessment of their walking capacity was found to reflect their general functional capacity. Thus the 62 who stated that they could walk over 1.5 kilometres had a far better over-all functional capacity than the remaining 63 (Fig. 9, Table XXI).

Twenty probands (16%) thought that they had recovered their walking capacity after the operation. 14 had been fused for unilateral and 6 for bilateral coxarthrosis. Only in 3 of the 20 cases were radiographic signs of progress in the mobile hip demonstrable.

Thirty-six probands (29%) claimed pain in the mobile hip to be the main cause of reduced walking ability. The index of radiographic

severity at the review was on the average 4.8 index points for these 36 hips with an average increase in index of 2.5 points. The pain index was 2.8 points.

Of the 63 probands who could only walk less than 1.5 kilometres 52 had pain and/or showed radiographic progress in the mobile hip. Reduced walking capacity was significantly more common among the bilateral cases (Table XXI).

Walking Outside Most of the 49 probands that used one stick carried it in the hand on the operated side. For the 58 probands who could walk unaided arthrotic progress was on the average 0.8 index point for the 49 using one stick 1.9 points for the 13 using two sticks 3.8 points and for the 5 probands using two trestles 1.8 point. That the progression among the 5 last probands using trestles was so slight was explained by the fact that only one of them used trestles because of symptoms in the mobile hip, whereas the rest used them mainly for balance outdoors. The latter 4 probands had markedly reduced mobility of the ipsilateral knee one of which was ankylosed as a result of an intraarticular fracture.

Only 35 probands stated that walking on snow or in slippery roads was not difficult whereas 65 had difficulties and 25 never went out alone in such weather. Twice as many probands had difficulties in walking uphill (78) as downhill (34) and 13 could manage neither.

Stairs Most of the probands had no difficulty in walking up or down stairs. Theoretically the smaller the angle of flexion in the fused hip the more difficult it is to climb stairs. In the present material no such correlation was found. Thirty-eight probands had trouble getting on a bus or a train and 19 could not do so without help.

Difficulties in getting into a car were common (43 probands) and many could only get in from one side i.e. with the mobile leg first. Some of the probands always had to sit in the front seat in order to have enough room for the stiff leg.

Toilet Seventy per cent of the probands could manage without much difficulty. One third of the total number of probands used a heightened toilet seat and 20 had put handles on the wall to facilitate sitting down and rising from the toilet.

Twenty-four of the females had difficulties when passing urine. Thus 21 were troubled by urine running down the stiff thigh and 9 of these plus 3 others were troubled by the stream of urine tending

Table XXI Comparison between 62 Probands with Walking Capacity of 1 500 metres or more and 63 Probands with less

Walking Distance	Umlat		Bilat		Number	Mean Age at Foll -up	Restriction of Function	Mean R Index at Foll -up	Mean Increase in Rad Index	Mean Pain Index	Sex

the operation. Many daily activities could be mastered only with difficulty and some had since the operation become unsurmountable obstacles, especially for the elderly probands. Stiffness of the fused hip in association with pain in other joints, particularly the mobile hip, were the most common reasons for all degrees of disability.

## 5 Conclusions

Arthrodesis of the hip proved to be an effective method of eliminating the invalidity caused by pain and contractures in the arthrotic joint. As a measure of this fact three fourths (92) of the probands had been able to resume work, most (59) of whom had returned to their former occupation.

However, arthrodesis of the arthrotic hip is generally performed in the latter half of life when adaptability to changed conditions has become decreased. Consequently probands with the primary form of coxarthrosis, particularly when bilateral, showed far less good functional results and the lowest rate of restored working capacity, whereas the opposite was true of probands with secondary coxarthrosis, especially those with unilateral affection.

It was concluded that as functional capacity after arthrodesis of the hip was largely dependent on age and painfree compensatory motion of adjoining joints, most important of which was the mobile hip, the total functional gain was often of a temporary character.

to run in front of the toilet bowl. For 19 of the women these difficulties were constant and quite distressing. Some of them always carried a plastic container in their bags when away from home to prevent embarrassment. Seven of the total number of probands had not been able to use a toilet seat heightener and three had ever since the operation used the toilet in a standing position.

Dressing Except for socks and shoes, dressing was not difficult for 98 (78%) of the probands.

Putting on sock and shoe on the operated side proved to be an obstacle for nearly all of the probands. This was frequently solved by the help of another person or by the use of special aids. Only four probands could tie the shoelace on the fused side.

In addition to socks and shoes, putting on trousers was the commonest difficulty. Many had learned to use special aids or their walking sticks upside-down as a hook to make this task easier. Daily dressing time was assessed to be normal for 39 probands (2-5 min), prolonged for 57 (5-10 min) and markedly prolonged for 29 (>10 min).

Bathing Eighty-three probands (66%) had more or less difficulties when taking a bath. Thirty-five were dependent on help, whereas others assumed a kneeling position or had special seats made for the bath. Still others had replaced the bath by a shower. All were dependent on help for cutting townails on the fused side.

#### 4 Discussion

In coxarthrosis loss of function is caused by pain, faulty positions and decrease in range of motion. By arthrodesis two factors are permanently abolished at the price of eliminating what useful motion there may have been left in the joint. But one of the paradoxes of arthrodesis of the hip was the fact that its first goal, i.e. complete abolishment of motion in the joint in order to increase the overall functional capacity of the individual imposed serious restrictions on his pursuits.

Most of the probands, who before the operation had been on the brink of permanent invalidity, were glad to have sacrificed the remaining motion in the joint to obtain freedom from pain. For others the 'completeness' of the stiffness had come as a shock and some of the probands had a period of mental depression after discharge when faced with the tasks of daily living and a few still bitterly regretted

The investigation comprised a registration of the static support pattern a comparative study of preoperative and follow up radiograms of the mobile hip and a clinical examination

The static support test was performed with the aid of two electronic scales one for each foot, which were calibrated to the weight of the proband. The difference in loading between the two scales during a certain period could then be calculated from the tracings on an ink-writer. The purpose of the test was to ascertain the static support pattern in free and in instructed modes of standing (cf p 13). The test lasted for 20 minutes.

The radiographic examination comprised radiograms of the hips, pelvis, lumbar spine and knees. The chief aims of the radiographic examination were a) to assess radiographic signs of arthrotic deterioration of the mobile hip by a comparison with the preoperative radiograms according to a numerical index (Table IV) and b) radiographic determination of the degree of ab- or adduction of the fused hip.

The clinical examination aimed chiefly at recording a) range of motion and degree of pain in the mobile hip b) degree of flexion of the fused hip c) state of lumbar spine and knees and d) the probands' accounts of their ability to perform daily activities and of their working capacity.

## Chapter III RESULTS

### A Static Support Test

The test showed that when standing easy for 10 minutes only 15% of the probands used the fused leg for support ( $> 60\%$  of 1) whereas both legs were loaded fairly evenly (40% 60% of 1) by 43% and the mobile leg was used for support by 42% of the probands.

There was a distinct difference in the support pattern according to the state of the mobile hip. Thus arthrotic changes and pain were significantly more prevalent in the cases with equal support and those who preferred the fused leg for support than in those who preferred the mobile leg. Further loading of the fused leg appeared to be facilitated by the neutral and adducted position of the fused hip and by shortening of the fused leg.

## Chapter I INTRODUCTION

Since the beginning of the century arthrodesis has been one of the leading methods used in the surgical treatment of coxarthrosis. According to many authors arthrodesis of one hip in bilateral coxarthrosis provides the patient with a supporting leg so that the mobile hip is correspondingly relieved from mechanical strain.

The aims of the investigation were to find a) to what extent the fused hip was used for static support b) the incidence rate and degree of radiographic deterioration of the mobile hip and c) the incidence and degree of pain in the mobile hip and the influence of pain on daily activities and working capacity.

## Chapter II MATERIAL AND METHODS

### A Classification

The cases were classified as unilateral or bilateral coxarthrosis on the basis of preoperative radiograms. Distinction between primary and secondary coxarthrosis was based on the history and on radiographic appearance.

### B Material

The investigation was based on a follow-up examination of 125 probands who had undergone arthrodesis of the hip 2 to 22 years previously (average 10 years) for unilateral or bilateral coxarthrosis in the two forms of the disease: the primary and secondary.

There were 77 females and 48 males. The average age was 52 years at the time of operation and 61 at the review. It was the same in both sexes. In 61 cases with primary coxarthrosis, mainly bilateral, the average age at the review was 66 years, and in 64 with secondary coxarthrosis, mainly unilateral, 57 years.

in a joint initially affected. On the basis of these findings and in comparison with Danielssons's (1964) series of unoperated cases (cf. p. 42) the prognosis of the mobile hip in bilateral coxarthrosis especially of the primary type was considered poor.

### C Clinical Examination

The working capacity and gross functional capacity was often improved or restored after healing of the arthrodesis. Ninety-two (74%) of the probands were able to resume work. 59 (47%) in their former occupations.

The extent and permanency of recovery was dependent on the state of other joints, especially the other hip, and on the proband's age. Consequently probands with the primary form of coxarthrosis particularly when bilateral, showed far less good functional results and the lowest rate of restored working capacity, whereas the opposite was true of those with secondary coxarthrosis especially in unilateral affection.

It was concluded that as long as the hip arthrodesed subject was relatively young with no other joints affected, the adverse effects of the arthrodesis were more easily neutralized. In the older age groups particularly in primary coxarthrosis the combined effects of advancing age and changes in the opposite hip frequently caused an early diminution of the functional gain achieved.

The instructed modes of standing showed that 90% of the probands could use either leg for support for a period of 2 minutes whereas nearly one third of the probands could not distribute body weight evenly between the legs for a period of 5 minutes. Even loading of both legs was rendered more difficult by large discrepancies in leg length.

The support pattern in Romberg's test revealed that most of the probands resumed their support pattern displayed in the first part of the test.

As regards the leg generally used for support in daily life the findings were in agreement with the opinion of 75% of the probands. Those whose opinion differed from the results showed no preference for either leg.

Compared with what may be considered normal the number of shifts was markedly small especially among those who showed a distinct preference for uneven loading.

It was concluded that the fused leg was generally not used for chief support in standing and did not afford relief of the mobile hip. The great majority of the probands had loaded mainly the mobile leg as long as it could be comfortably used for this purpose.

## B Radiographic Examination

The radiographic examination revealed signs of arthrotic deterioration of half of the mobile hips and that the prognosis of the mobile hip was not uniform.

A marked difference depending chiefly on two factors was observed: i.e. whether or not the mobile hip was initially affected with arthrotic changes and whether the other hip had been fused for primary or secondary arthrosis. This strongly suggested that the dominant factor deciding the future of the mobile joint was of biological nature. Thus the mobile hip fared best in the absence of the above factors and by far worst in the presence of both.

The frequency and severity of radiographic changes in the mobile hip when initially affected did not suggest relief of its weight bearing functions by the fused hip. Far from being unburdened by the fusion of the opposite hip the mobile hip was subjected to heavy compensatory strain under both static and dynamic conditions which with time generally resulted in degenerative changes in the joint when biologically susceptible. In no instance were signs of regression demonstrable.

## INTRODUCTION

Although samples of patients with peripheral arterial insufficiency chosen by different methods and with different criteria have been described, no attempts have been made to relate the frequency of these diseases to the population at risk. PERLOW (1962) stated: "Although most people over 60 years of age have some degree of arteriosclerosis, no statistics are available on the number who have circulatory impairment in the lower extremities." Arteriosclerotic changes are becoming more frequent with increasing age (STERNBY 1968). SOLTU et al. (1957) thought that the observed increase of pathological changes in the arteries was caused by increasing survival in the population and he felt that after the age of 70 almost everybody had degenerative arterial disease.

Also, arterial changes in conjunction with diabetes mellitus have been studied and KRAVER and PERILSTEIN (1958) claimed that these conditions have increased between 1921 and 1956. On the other hand BELL (1957) found that the incidence of gangrene in diabetes mellitus decreased during the first half of this century.

It has been suspected that the true incidence of arteriosclerotic changes in the lower limbs is increasing. In the Department of Orthopaedic Surgery in the General Hospital, Malmö, the proportion of patients treated for peripheral arterial insufficiency as well as the number of beds occupied by these cases have increased.

However, this is not sufficient evidence of a true increase in the incidence of this disease. All hospital facilities in the city as well as changes in the distribution of the population at risk would have to be included in a survey of incidence changes. Malmö has previously proved to be suitable for epidemiological studies as demonstrated by BJÖRCK (1955), HALL (1961), SIVÉN (1963), ALFFRAM and BAUER (1962), ALFFRAM (1964), BERGE

## INTRODUCTION

Although samples of patients with peripheral arterial insufficiency chosen by different methods and with different criteria have been described, no attempts have been made to relate the frequency of these diseases to the population at risk. PERLOW (1962) stated: "Although most people over 60 years of age have some degree of arteriosclerosis, no statistics are available on the number who have circulatory impairment in the lower extremities." Arteriosclerotic changes are becoming more frequent with increasing age (STENNEY 1968). SOLTU et al. (1957) thought that the observed increase of pathological changes in the arteries was caused by increasing survival in the population and he felt that after the age of 70 almost everybody had degenerative arterial disease.

Also, arterial changes in conjunction with diabetes mellitus have been studied and KRAMER and PERILSTEIN (1958) claimed that these conditions have increased between 1921 and 1956. On the other hand BELL (1957) found that the incidence of gangrene in diabetes mellitus decreased during the first half of this century.

It has been suspected that the true incidence of arteriosclerotic changes in the lower limbs is increasing. In the Department of Orthopaedic Surgery in the General Hospital, Malmö, the proportion of patients treated for peripheral arterial insufficiency as well as the number of beds occupied by these cases have increased.

However, this is not sufficient evidence of a true increase in the incidence of this disease. All hospital facilities in the city as well as changes in the distribution of the population at risk would have to be included in a survey of incidence changes. Malmö has previously proved to be suitable for epidemiological studies as demonstrated by BJÖRCK (1955), HALL (1961), SIFVERS (1963), ALFFRAM and BAUFER (1962), ALFFRAM (1964), BERGE

(1967) and STERNBY (1968) dealing with problems ranging from rheumatic fever and coronary disease to fractures, cancer and atherosclerosis.

The objective of the present study was to calculate age and sex specific incidence for the major groups of conditions leading to peripheral arterial insufficiency and to study possible changes over a 17-year period. Against the background of the hospital facilities in the city it should also be possible to estimate some socio-economic implications of this group of diseases.

## MATERIAL AND METHODS

### THE CITY OF MALMÖ

The city of Malmö, the third in population in Sweden, is a center of industry and trade. From the end of 1918 to the end of 1965 the population increased from 185,947 to 249,161,<sup>1</sup> the increase being comparatively steady over the years (Table 1).

Table 1. *The population of Malmö 1948—1965.*

	Men	Women	Total
1948	87,635	98,312	185,947
1949	89,298	99,934	189,232
1950	91,111	100,672	191,783
1951	93,572	102,918	196,490
1952	94,807	103,838	198,645
1953	96,404	105,535	201,939
1954	98,282	107,358	205,640
1955	100,301	109,172	209,473
1956	102,358	110,902	213,260
1957	104,429	112,901	217,330
1958	106,622	115,078	221,700
1959	108,685	116,975	225,660
1960	110,473	118,775	229,248
1961	112,708	120,644	233,352
1962	114,890	122,627	237,517
1963	117,140	124,638	241,778
1964	118,930	126,873	245,803
1965	120,757	128,404	249,161

During these 17 years population census was carried out in 1950, 1960 and 1965. The distribution of age and sex in the population in these three surveys is shown in Table 2.

<sup>1</sup> Department of Statistics, Financial Committee of Malmö.

## HOSPITAL FACILITIES

In the city of Malmö almost all hospital facilities are owned by the community and financed by city and state funds including the compulsory state health insurance. On the whole, there are very few private or voluntary hospitals in Sweden and these only in the large cities. In the city of Malmö there are two private nursing homes with altogether 37 beds and facilities for the care of simple cases of chronic disease.

Hospitalization is free of charge except for the care of chronic somatic disease where after six months of hospitalization a small sum, well within the limits of the general pension, is charged.

The city constitutes a defined area for health care with a central administration for the three municipal hospitals: Malmö Allmänna Sjukhus (MAS) for mainly emergency and short time somatic disease, Värnhemss Sjukhus (VÄS) for chronic somatic disease, and Malmö Östra Sjukhus (MÖS) for mental disease. MAS is a teaching hospital affiliated to the

1950	1,373	216	571	298	731	381
1960	1,544	674	679	274	872	380
1965	1,631	655	682	274	837	336

University of Lund and receives patients also referred from other districts in the southern part of the country.

Over the years, the number of hospital beds decreased in relation to the population (Table 3). While the number of somatic hospital beds increased by 19 % and the number of beds for chronic somatic disease by 20 % between 1950 and 1965, the population increased by 29 %. In addition, the age distribution during the same period shifted towards higher age groups; the cases of the present study were rarely younger than 45 years at first admission and between 1950 and 1965 the number of residents over 45 increased by 51 %, as compared to 29 % in the total population.

### CRITERIA

To be included in the study patients had to answer the following criteria:

- Hospitalization should be caused exclusively by symptoms of peripheral arterial insufficiency in the legs.
- The patient should have been admitted to a hospital in the city during the years 1949—1965.
- The patient should at the time of admittance be a resident of the city.

### COMMENT

Cases with peripheral arterial insufficiency have been admitted to the Departments of Orthopaedic Surgery, General Surgery, Internal Medicine, Dermatology and Infectious Disease at the MAS. Patients admitted to the VÄS and to the Department of Chronic Somatic Disease at the MAS have been presented under the same heading—Department of Chronic Somatic Disease. Altogether 10 patients in treatment for peripheral arterial insufficiency were discharged from somatic departments at the MAS to the MÖS where they were treated mainly because of their mental

and in some instances supported by angiography or histological examination.

d) **Arterial embolism:** Includes cases with sudden onset of symptoms of arterial occlusion in patients without previous history of symptoms of peripheral arterial insufficiency. All of these patients had a history of cardiac disease such as fibrillation or mitral stenosis, in addition, some had a history of emboli to other organs. Twelve patients in this group also had a history of diabetes mellitus but without previous symptoms of peripheral arterial insufficiency.

Arterial thrombosis was not used as a diagnosis in this study. Cases with a history of chronic peripheral arterial insufficiency with sudden impairment were included in the group of arteriosclerosis obliterans.

### DATA REPRESENTATION AND STATISTICAL ANALYSIS<sup>1</sup>

Patients who were admitted to hospital because of symptoms of peripheral arterial insufficiency for the first time during the period covered by this study, 1949—1965, are referred to as *first admissions*. When analysing demands on hospital facilities during this period also patients admitted to hospital because of peripheral arterial insufficiency, who already before 1949 had previously been admitted to hospital for the same condition, were included.

The average population of the city for the years 1949—1965 was calculated in the following manner:

Sex-distribution and age-distribution in age-groups of five years were known from census on December 31, 1950, November 1, 1960 and November 1, 1965 and were calculated for men and women separately as follows:

	Dec. 31, 1950	Nov. 1, 1960	Nov. 1, 1965
Men 30—34	a	b	c

Average population of men 30—34 =  $\frac{2a+3b+c}{6}$ .

The average frequency of first admissions for each age-group was obtained by dividing the number of first admissions in the group by the calculated average population and expressed as number of cases per 100,000.

The computation of the expected increase of first admissions during the

<sup>1</sup> Statistical adviser was professor Carl-Erik Quensel, Department of Statistics, University of Lund.

For the analysis of the data programming and computer services were provided by the city of Malmö and Data-SÅAB, Linköping.

easily available which provides opportunities for cross-checking and back-checking of the history in each case. The panorama of peripheral arterial insufficiency in the legs can therefore be presented as completely as is possible in a retrospective study.

For administrative reasons the residency of the patients is an important item in the record and was therefore available and correct. Patients who had been referred from other districts in southern Sweden were not included in the study.

In many cases it was not possible to decide in retrospect whether or not irreversible gangrene had been present at the time of first admission. However, about 90 % of the arteriosclerotics had such gangrenous changes and almost all the diabetics.

## CLASSIFICATION

The patients were classified in four groups:

- a) *Arteriosclerosis obliterans*: Patients with symptoms of chronic peripheral arterial insufficiency without diabetes mellitus.
- b) *Diabetes mellitus*: Patients with symptoms of chronic peripheral arterial insufficiency and with diabetes mellitus.
- c) *Thrombangitis obliterans*: Patients with symptoms of chronic peripheral arterial insufficiency diagnosed as thrombangitis obliterans.
- d) *Arterial embolism*: Patients with sudden onset of symptoms of peripheral arterial insufficiency.

## COMMENT

a) *Arteriosclerosis obliterans*: Includes cases with a history of peripheral arterial insufficiency with a gradual onset. None of the patients in this group had diabetes at the time of first admission but in a few this condition was diagnosed later on.

b) *Diabetes mellitus*: Includes patients with the same type of symptoms as in arteriosclerosis obliterans who had or received the diagnosis of diabetes mellitus at the time of first admission. No attempt was made to differentiate between pathological changes caused by the specific diabetic microangiopathy and of arteriosclerotic changes in the large vessels of these patients, the effect of diabetes mellitus and possible concomitant arteriosclerotic disease was studied as an entity.

c) *Thrombangitis obliterans*: Includes patients who, at the time of first admission, received the diagnosis of thrombangitis obliterans. The diagnosis was mainly based on clinical criteria including age and sex (young men)

## RESULTS

There were 967 first admissions, 550 men and 417 women distributed between the four diagnosis as demonstrated in Table 4.

### AGE AND SEX SPECIFIC INCIDENCE

#### PREVIOUS STUDIES

DRY and HINES (1941), HAIMOVICI (1950), KRAMER and PERILSTEIN (1955 and 1958), SPAULDING (1956), BLOOR (1961), SCHADT et al. (1961), BADDELEY and FULFORD (1965), BUGÁR-MÉZÁROS and BERECKZY (1966), PREUSS et al. (1969) and NIELSEN (1969) used the time of *first onset of symptoms* of peripheral vascular disease in the leg for calculation of age distribution. For the same purpose, SEMPLIE (1953), OAKLEY et al. (1956), KAYE et al. (1963), GENSLE et al. (1965) and HAIMOVICI (1967) used the point in time when the patients *first sought medical advice*. The age at which *manifest gangrene* occurred was used by ELIASON and WRIGHT (1926), KRAMER (1932), JOHN (1938), McLAUGHLIN (1943), McLAUGHLIN and WIEDMAN (1950), BÜRGER (1954) and McLAUGHLIN and HEIDER (1955). —SILBERT and HAIMOVICI (1950), SEUMACKER and MOORE (1951), CLAUGUS et al. (1958), WRIGHT (1960), HANSSON (1964), BRADHAM and SMOAK (1965), OTTEMAN and STAHLGREN (1965) and LINDAHL and BOLUND (1969) calculated the age distribution at *amputation* in cases with peripheral arterial occlusion. BELL (1950 and 1957) calculated the age distribution of subjects with gangrene in an *autopsy* material.

The resulting age distributions have differed considerably between the authors depending on the point in the natural history of the disease chosen and the types of vascular disease included. However, also clinical materials which appear to be similar give varying results with regard to age-distribution.

JOHN (1938) surveying the literature found that the average age at the *début* of diabetic gangrene varied from 51 to 70 years. SCHADT et al. (1961) found that the average age at *début* of vascular symptoms in diabetics was 52 years and in a mixed group of patients suffering from arteriosclerosis obliterans and diabetes mellitus 56 for men and 61 for women. On the whole, the majority of patients with peripheral arterial disease in

years 1949—1965 because of the changes in number and the shift towards higher ages in the population was made from the known distributions of 1950, 1960 and 1965.

For significance test standard statistical methods have been used, levels of probability of 99 % or better have been referred to as significant.

In order to study what changes have occurred during the 17 years covered by the study the period has been divided into three intervals 1949—1954, 1955—1960 and 1961—1965.

## THROMBANGITIS OBLITERANS

Fig. 2

Age and sex specific incidence of thrombangitis obliterans.

## ARTERIAL EMBOLISM

Fig. 3

Age and sex specific incidence of arterial embolism.

of the period. In diabetes mellitus some border-line significant fluctuations were observed but no consistent tendency.

Cases with arterial embolism were significantly older in the later part of the period, men as well as women.

For arterio-sclerosis obliterans there was an increasing incidence throughout life in both sexes, the raise in incidence occurred about 10 years later in life in women as compared to men (Figure 1). In the diabetics there was no sex difference and the incidence did not increase further after the eighth decade.

The data on the incidence of thrombangitis obliterans and arterial embolism (Figures 2 and 3) do not permit comparison between groups or sexes. However, the deviation in the incidence pattern of thrombangitis obliterans is obvious.

These data have been calculated and presented without regard to possible changes over the years. As demonstrated below there have been considerable changes in the incidence of peripheral arterial insufficiency.

In Figures 4—10 the observed numbers per year, sex and diagnosis have been presented graphically and related to the change expected from changes in the population. It was found that in men with arteriosclerosis obliterans the observed numbers increased over the years considerably more than could be predicted from the expected values. The same, although to a less degree, was found in arterio-sclerotic women. In diabetes mellitus

Table 6. Age at first admission (Average  $\pm$ SD).

		1949-1954	1955-1960	1961-1965	1949-1965
Arteriosclerosis obliterans	Men	69 $\pm$ 11	67 $\pm$ 12	68 $\pm$ 12	68 $\pm$ 12
	Women	73 $\pm$ 9	75 $\pm$ 9	79 $\pm$ 10	76 $\pm$ 10
Diabetes mellitus	Men	67 $\pm$ 8	70 $\pm$ 8	67 $\pm$ 11	68 $\pm$ 10
	Women	68 $\pm$ 8	68 $\pm$ 10	71 $\pm$ 7	69 $\pm$ 9
Thrombangitis obliterans	Men	47 $\pm$ 12	50 $\pm$ 10	39 $\pm$ 3	47 $\pm$ 11
	Women	—	—	—	—
Arterial embolism	Men	64 $\pm$ 13	66 $\pm$ 10	74 $\pm$ 10	68 $\pm$ 12
	Women	63 $\pm$ 10	70 $\pm$ 13	76 $\pm$ 9	72 $\pm$ 13

In the present study women with arteriosclerosis obliterans were on the average eight years older than men with the same disease. The difference was significant (Table 6). In cases with diabetes mellitus and in cases with arterial embolism there was no significant difference between the sexes.

Women with arteriosclerosis obliterans were on the average seven years older than women with diabetes mellitus, the difference was significant.

Over the 17 years covered by the study there was no significant change in age at the time of the first admission in men with arteriosclerosis obliterans. Women with this disease were significantly older during the later part

observed numbers of cases of women with  
arterial embolism.

### COMMENT

Peripheral arterial insufficiency has increased in rate in the city and the increase exceeds the increase expected from changes in the population. The increase was most marked although not entirely confined to arteriosclerosis obliterans so that this disease has become the most common in the group, although diabetes mellitus previously has been considered to be, and—during the early part of this study was—the most important condition causing arterial disease in the legs.

During the time of this investigation Eros et al. (1953) demonstrated

## ARTERIOSCLEROSIS OBLITERANS

Fig. 4

## ARTERIOSCLEROSIS OBLITERANS

Fig. 5  
Comparison between expected and observed numbers of cases of women with arteriosclerosis obliterans.

a similar tendency was found for men but considerably less than in arteriosclerosis obliterans. In diabetic women the observed number agreed with the expected. Thrombngitis obliterans became a less common diagnosis over the years. The observed rate of men with arterial embolism agreed with the expected number, in women the observed number seemed to increase somewhat above the expected.

significant preponderance for left-side affection. These independent observations taken together probably indicate a true preponderance for left-side onset in these conditions.

## INVOLVEMENT OF THE CONTRA-LATERAL LIMB

### PREVIOUS STUDIES

HASSE (1959) found a bilateral onset of claudication in 18 % of his cases, within one year 61 % had bilateral claudication, within two years 76 % and within five years 92 %.

In an autopsy material BELL (1957) found bilateral cases in 21 % with arteriosclerotic gangrene and in 26 % with diabetic gangrene. In bilaterally amputated cases the interval between the amputations had varied between one month and seven years. CARVEY and GOLDOWSKY (1957) found that the average interval between amputations because of gangrene was 1.5 years. OTTFMAN and STAHLGREN (1965) found the same interval to be on the average 2.5 years.

BANDELEY and FILLFORD (1965) found that one fifth of unilaterally amputated diabetics within three years had been amputated on the contralateral leg.

RICHSEN (1966) found the average interval between the two amputations in bilaterally amputated diabetics to be 21 months.

that arteriosclerosis occurred in men as young as 20 years of age. Some of the young patients with the diagnosis of thrombangitis obliterans during the first years of this investigation may thus have been young arteriosclerotics. The changes in age and incidence over the years for these patients seem to support this hypothesis.

## LEFT—RIGHT VARIATION

### PREVIOUS STUDIES

The pathological changes in these conditions usually are bilateral, even if signs or symptoms of the disease usually become obvious in one limb before the other.

HASSE (1959) found in a series of 1,406 men with claudication onset of symptoms on the left side in 44 %, on the right side in 38 % and bilateral in 18 %, there being no marked side difference. Nor could the same author find any left or right preponderance for arterial occlusion or for the first sign of gangrene.

KRAUTWALD and VÖLPEL (1959) presented 722 patients with various symptoms of arterial insufficiency in the legs, nine per cent of whom were women. There were symptoms from altogether 1,166 legs, 595 left legs and 561 right legs. The difference was not significant.

KAYE et al. (1963) found in a series of arteriographies of 269 patients with arterial insufficiency no side difference neither with regard to occlusion nor to atheromatos lesions.

ELIASON and WRIGHT (1926) found in 100 cases of gangrene of the legs in arteriosclerotic and diabetic patients right side affection in 46, left side in 45 and bilateral in three.

WESSLER et al. (1958) found in 75 patients with 69 episodes of arterial embolism in the legs 45 left-sided and 28 right-sided affections, eight were located in the bifurcation.

### PRESENT STUDY

In 957 first admissions in the present study the left—right localization was clearly stated. There were 365 cases right-sided, 398 left-sided and 194 bilateral cases (Table 7). There were no significant differences between sexes, between the four diagnostic groups or in the total material.

### COMMENT

It should be noticed that in the majority of the data presented in medical literature as well as in the present study there is a slight but usually not

Table 7. *Left-right localization at the first admission.*

## DIABETES

Fig 15.  
Seasonal variation  
of admissions for  
women with diabetes  
mellitus.

## COMMENT

There is a tendency of seasonal variation characterized by a decreased incidence in the spring and in the summer. This variation is more pronounced for men and somewhat more in arterio-sclerosis obliterans than in diabetes mellitus. However, the variation usually does not reach a level of significance which permits statistical comparisons between the subsets. In thrombangeitis obliterans and arterial embolism no pattern of seasonal variation could be distinguished.

The time lag between onset of symptoms or impairment and admission may vary considerably, and therefore the first admission should probably not be regarded as a biological parameter reflecting a true seasonal variation of the disease.

## AGE AT DEBUT OF DIABETES MELLITUS

## PREVIOUS STUDIES

Although diabetes may be diagnosed at any age the debut in most patients is between 40 and 70. SPIEGELMANN and MARKS (1946), PYKE (1956), REICHMANN et al. (1958), SCHLACK (1959) and JUNG et al. (1968) published somewhat varying figures with respect to the onset of diabetes but all agreed that onset of the disease usually occurred in the middle-aged.

Data derived from authors who have presented their age distribution in age groups are presented in Table 9 and 10.

OAKLEY and CONLEY (1951-1955) and GOLDNER (1960) did not find a single case in which the diabetes had originated before the age of 20 among their patients with peripheral vascular disease of the lower limb.

Table 9. *Age at debut of diabetes mellitus, per cent of the patients.*

Authors	Observation period	No.	Age at debut of diabetes mellitus

Among 3,500 cases of arterial occlusion in the legs DEBAKEY et al. (1964) found only six patients with juvenile diabetes.

#### PRESENT STUDY

The percentual distribution of age at onset of diabetes in individuals who had their first admission during the years 1949 to 1965 are presented in Table 9 and compared to a series of individuals amputated because of diabetic gangrene (HANSSON 1964) and to data presented by other authors on individuals about whom it is not known whether they had developed vascular complications or not. There was a significant tendency of higher ages in the present series as compared to the other series with one exception, HANSSON (1964), who also dealt with cases of vascular complications in the lower limbs. In Table 10 the data of the present study are compared with respect to age distribution within the sexes and to similar data in diabetics without known vascular complication. The differences between the sexes in age at onset of diabetes were not consistent. In the present study the women had been significantly older at the time of onset of diabetes than had the men (Table 11). There was no change in this respect between the three periods of the study.

Table 10. Age at début of diabetes mellitus in men and women, per cent of the patients.

Authors	Observation period	No	Sex	Age at début of diabetes mellitus								80+

## COMMENT

The study of Hansson and the present study differ from the other studies with respect to the proportion of patients with début of diabetes mellitus before the age of 40. The former studies include only amputated patients and patients admitted to hospital because of symptoms of peripheral arterial insufficiency, the latter are based on diabetics without special reference to peripheral vascular disease. The difference is due to the small number of juvenile diabetics among cases with peripheral vascular complica-

Among 3,500 cases of arterial occlusion in the legs DEBAKEY et al. (1964) found only six patients with juvenile diabetes.

#### PRESENT STUDY

The percentual distribution of age at onset of diabetes in individuals who had their first admission during the years 1949 to 1965 are presented in Table 9 and compared to a series of individuals amputated because of diabetic gangrene (HANSSON 1964) and to data presented by other authors on individuals about whom it is not known whether they had developed vascular complications or not. There was a significant tendency of higher ages in the present series as compared to the other series with one exception, HANSSON (1964), who also dealt with cases of vascular complications in the lower limbs. In Table 10 the data of the present study are compared with respect to age distribution within the sexes and to similar data in diabetics without known vascular complication. The differences between the sexes in age at onset of diabetes were not consistent. In the present study the women had been significantly older at the time of onset of diabetes than had the men (Table 11). There was no change in this respect between the three periods of the study.

Table 12 *Timing between the diagnosis of diabetes mellitus and severe symptoms of peripheral vascular insufficiency.*

tion. In the series of Hansson and in the present series 82 and 78 per cent of the patients, respectively, were over 50 at the début of diabetes mellitus as compared to 58 % in the series of Silwer.

## TIME-LAG BETWEEN THE DIAGNOSIS OF DIABETES MELLITUS AND FIRST ADMISSION FOR PERIPHERAL ARTERIAL INSUFFICIENCY

### PREVIOUS STUDIES

CONWAY and MEIGHER (1942) found an average interval of eight years between the début of diabetes and the first signs of vascular foot lesion and in 20 % of the cases the diabetes was not diagnosed prior to the occurrence of vascular symptoms. BLOCK and WHITEHOUSE (1963) calculated the same variable to be 12,5 years, BRYFOGLE and BRADLEY (1957) to 14 years and HANSSON (1964) to nine years. Authors who have presented the time intervals as distributions are referred to in Table 12.

BADDELEY and FULFORD (1965) found in a series of amputated diabetics that in 39 % the diagnosis of diabetes had been made one year or less before the operation. BARTELS and RULLO (1958) found in patients with symptoms of peripheral arterial insufficiency without previously known diabetes that only 23 % had completely normal glucose-tolerance tests and 20 % were diabetics. JOSLIN (1934) found that patients with diabetes who died with gangrene in the lower limb on the average had had their diabetes for 10 years.

### PRESENT STUDY

In the present study the average interval between the début of diabetes and the first admission was 9,6 years, 10,7 for men and 8,7 for women, significantly shorter for women. The time variable was skewedly distributed and is presented in Figure 16. Table 12 presents a comparison between the present series and previous studies in this respect. In 20 % of the cases in the present series the diagnosis of diabetes had not been made prior to the first admission which is one of the highest fractions observed.

### COMMENT

The sampling process is not uniformly defined in the studies listed in Table 12 but include various stages of arterial insufficiency. VISKUM (1969) dealt with cases of manifest gangrene. GOLDNER et al. (1959) and HANSSON (1964) described amputated diabetics. Only in the present study the first admission because of peripheral arterial insufficiency was used to

Starting from the *début* of symptoms of peripheral arterial insufficiency SILBERT and ZAZEELA (1958) found that the 10-year survival for diabetics was 62 % and for non-diabetics 80 %, the mortality was particularly increased in diabetics between 40 and 50, while in the same age-group of non-diabetic patients, the survival did not differ from that of the base population.

Using the *first consultation* because of symptoms of peripheral arterial insufficiency HINFE and BARKER (1930) found that 45 % survived for three years. BOYD and BLOOR (1939) had a five year survival of 74 %, a 10 year survival of 39 % and 15 year survival of 22 %.

In cases with femoro-popliteal occlusions verified by angiography SINGER and ROB (1960) had a five year survival of 81 %. For patients with aorto-iliacal occlusion the figure was 69 %.

Calculated from the *time of the diagnosis* JURUGEN, BARKER and HINFE (1960) found that in cases of femoro-arterial occlusion caused by arteriosclerosis obliterans the five year survival was 80 % and the 10 year survival 57 %, for aorto-iliacal occlusion the figures were 73 and 47 respectively.

In *gangrene* HFINE and SCHWIDT (1966) found a survival of 27 % after four and a half years.

LAXON (1939) found in patients with *peripheral arterial insufficiency* a five year survival of 38 % in arteriosclerosis obliterans, 39 % in diabetes mellitus and 85 % in thrombngitis obliterans. MAZER (1967) published the survival rates for diabetics and non-diabetics sampled from several hospitals. Most findings are in agreement with the statement by SKVINSKY and ZISLIS (1970) that "the outlook for longevity of diabetic amputees and non-diabetic amputees is similar."

SILBERT and HAIMOVICI (1950), DALE and CAPEN (1959), ROSENBERG et al. (1970) and THURNBY and DUNN (1970) all described the survival following *amputation* because of peripheral arterial insufficiency with varying results.

McKITTICK (1940) found 55 % survival after three years in cases with *diabetic gangrene*. After five years the figure was 47 %. SILBERT (1948) compiled the three year survival after femur amputation in diabetics from several hospitals to be 40 %. However, later he (SILBERT 1952) found that the figure had increased to 65 %.

Similarly, SMITH (1956), WRIGHT (1960), BLOCK and WHITTHOUSE (1963), BADDLEY and FULFORD (1965), WHITTHOUSE et al. (1968) and VISKIN (1969) have presented survival rates in cases with *diabetic gangrene* within the same order of magnitude as presented above.

WRASLER et al. (1958) in a series of arterial embolism found that 21 % died in hospital, and that the three year survival was about 50 %.

PER CENT OF GROUP

Fig. 16

terminate the time lag. The patients of this series have all reached the point when their peripheral arterial disease necessitated hospital admission. All of them were not amputated on during the first admission and the attitude to treatment of these patients has been fairly conservative and similar to that in the series of Viskum. In this and the present study there were 20 % cases of undiagnosed diabetes. Only in two other previous studies, CONWAY and MEIGER (1912) and BADDELEY and FULFORD (1965), similar percentages were noted.

## SURVIVAL

### PREVIOUS STUDIES

Survival has been calculated from various points in time in the natural history of peripheral arterial disease.

77 % and for women 57 %, one year survival for men 68 % and for women 45 %, three year survival for men 56 % and for women 27 % and five year survival for men 48 % and for women 24 %.

There was no difference between men and women in cases with diabetes (Figure 18). The survival at three months, one year, three years and five years were for men and for women 90 and 85 %, 73 and 69 %, 47 and 49 % and 37 and 31 %, respectively.

Except for differences between the sexes it can be seen that there were significant differences between diabetes mellitus and arteriosclerosis obliterans. Arteriosclerotic men had a longer survival than had diabetic men, arteriosclerotic women, however, had a shorter survival than had diabetic women.

In thrombangitis obliterans the survival probably did not differ from that of the population by large (Figure 19).

Cases of arterial embolism had a three months survival of only 50 % and the one year survival was the same as for arteriosclerotic women, 45 % (Figure 20). This former group of patients has been established to have a poor life expectancy mainly because of the risk of repeated emboli to other organs. (HAIMOVICI 1950 and WESSLER et al. 1958).

#### COMMENT

For part of the cases the follow-up time was less than five years. In order to compare possible changes in survival over the years and to study

Fig. 17

Survival of men and women with arteriosclerosis obliterans and with first admissions 1949-1965, per cent of group.

#### PRESENT STUDY

For the purpose of studying survival, all individuals who had their first admission during 1949-1965 were followed up to at least July 31, 1967, the follow-up being complete up to that date.

In arteriosclerosis obliterans there was a considerable difference in survival between the sexes (Figure 17). Three months survival was for men

Fig. 18

Survival of men and women with diabetes mellitus and with first admissions 1949-1965, per cent of group.

77 % and for women 57 %, one year survival for men 68 % and for women 45 %, three year survival for men 56 % and for women 27 % and five year survival for men 48 % and for women 24 %.

There was no difference between men and women in cases with diabetes (Figure 18). The survival at three months, one year, three years and five years were for men and for women 90 and 85 %, 73 and 69 %, 47 and 49 % and 37 and 31 %, respectively.

Except for differences between the sexes it can be seen that there were significant differences between diabetes mellitus and arteriosclerosis obliterans. Arteriosclerotic men had a longer survival than had diabetic men, arteriosclerotic women, however, had a shorter survival than had diabetic women.

In thrombangitis obliterans the survival probably did not differ from that of the population by large (Figure 19).

Cases of arterial embolism had a three months survival of only 50 % and the one year survival was the same as for arteriosclerotic women, 45 % (Figure 20). This former group of patients has been established to have a poor life expectancy mainly because of the risk of repeated emboli to other organs. (HAIMOVICI 1950 and WESSLER et al. 1958).

#### COMMENT

For part of the cases the follow-up time was less than five years. In order to compare possible changes in survival over the years and to study

Fig. 22

Survival of patients with diabetes mellitus and with first admissions 1949-1954, 1955-1960, 1961-1965, per cent of group.

death rate in the first months was comparatively high, but from there on the mortality curve flattens out more than in the diabetics. This difference between the diagnoses was most pronounced in women (Figures 17 and 18, p. 33). The short survival of arteriosclerotic women as compared to men is explained by the age-dependent decrease in life expectancy. The women who died within one year after the first admission were five years older than the average age for arteriosclerotic women.

## DEMANDS ON HOSPITAL FACILITIES

### PREVIOUS STUDIES

The average length of hospital stay for patients admitted because of symptoms of peripheral arterial disease in diabetics or arteriosclerotics has been presented by several authors, ELIASON and WRIGHT (1926), MCKITTRICK (1940), McLAUGHLIN and HEIDER (1955), ROOF et al. (1955), CARNEY and GOLDBOWSKY (1957), CARVE et al. (1967), WARREN and KINN (1968). In these studies only one admission is recorded for each patient and the average length of stay varies between 23 and 206 days depending on factors such as the selection of cases, the level of amputation and the rehabilitating resources. CAMERON et al. (1964) in a series of 47 diabetic patients with 67 admissions because of amputation found an average length of stay of 65 days and a total of time spent in hospital after amputa-

tion of 89 days. Sixteen patients who died in hospital after amputation were not included. VISKUM (1969), reviewing a conservatively treated series of diabetic gangrene with an average observation time of 3,8 years found the average length of initial stay in hospital to be 77 days and a total average hospital stay for each patient of 146 days.

There are no studies presented demonstrating the annual or accumulated number of days in hospital for patients with peripheral arterial insufficiency in a defined population at risk. Nor are data available on possible changes with time of the demands on hospital facilities.

### PRESENT STUDY

In the calculation of the demands on hospital facilities from patients with peripheral arterial insufficiency all 2,243 admissions over the period were used. This also included 89 patients who had been admitted for the first time before 1949.

For the patients in these complete series the annual demand for hospital days was more than tripled during the time under study (Figure 23). During the same time the population of the city increased by one third.

The changes in different groups were in accordance with changes in incidence.

Fig. 23  
Days in hospital  
required annually  
by patients with  
peripheral arterial  
insufficiency.

hospital days as compared to 1.96 % in 1965. Again, this points out that the number of patients was tripled and the number of hospital beds available largely unchanged: with an increase in the population 1949—1965 by one third went a 200 % increase of the hospital beds needed by these patients.

To some extent the demands for hospital beds for this category of patients may be related to survival. There was, however, not sufficient change in the rate of survival of these patients to explain the change in the need for hospital beds. Also patients with comparatively short survival rates such as the arteriosclerotic women did not as a group accumulate fewer hospital days over the years than arteriosclerotic men with a better short time survival. Men with diabetes mellitus had a survival very similar to women but accumulated over the years about 50 % more hospital days than the women (Table 16).

Table 15. *Annual hospital days for patients with peripheral arterial insufficiency in relation to all available and per 100,000 inhabitants.*

Year	Total number	%	Number per 100,000 inhabitants
1949	4,400/645,796	=0.68	2,380
1965	13,750/700,592	=1.96	5,520

than arteriosclerotics or the other groups. Men had shorter admissions in all groups in the somatic departments but not in the chronic somatic departments.

During 1949—1965 totally 960 patients were discharged from their first admission (Table 14). About half of these patients could return to their homes, and in addition a few per cent were discharged to homes for the aged or for convalescents. One fifth were discharged to other somatic departments. About seven per cent were directly transferred to the Department of Chronic Somatic Disease, a rather small number considering the fact that this department becomes the end station for so many of these patients. One fifth of the patients died during the first admission.

There was an obvious sex difference in cases with arteriosclerosis obliterans. Considerably fewer women could return to their homes and more than 40 % died.

#### COMMENT

The increase in incidence found in the present study may also be put in relation to the total hospital facilities (Table 15). The total requirement of hospital days for patients of this kind was in 1949 0.68 % of the available

Table 16. *Average accumulated number of hospital days per patient.*

	Men	Women
Arteriosclerosis obliterans	101	137
Diabetes mellitus	214	139
Thrombangitis obliterans	103	48
Arterial embolism	63	57

Systematic changes in the indications for hospital admission over the years could not be demonstrated. No new therapeutic measures have changed the indications for hospitalization. The attitude towards vascular surgery has been very restricted in Malmö. The number of hospital beds available decreased in relation to the population. The duration of each hospitalization did not increase.

These findings indicate indirectly that no major changes in the attitude towards hospitalization of these cases have taken place.

### ASPECTS ON ARTERIOSCLEROSIS

The most prominent finding in the present study was the increase in incidence of arteriosclerosis obliterans in the lower limb in men. In the same population STERNBY (1968) found in autopsies that arteriosclerotic changes were observed earlier in life and also were more common in men than in women. In clinical material including cases amputated because of arterial insufficiency several investigators (CARVEY and GOLDOWSKY 1957, ALFRAM and HOLMQUIST 1961, PERLOW 1962, GENSLER et al. 1965, MITTY and ALMEIDA 1967, HAIMOVICI 1967) found that the diabetics constituted half or more of their respective cases. In the early years of the present study diabetes was the most important condition in the group of disease causing peripheral vascular insufficiency, but later on, arteriosclerosis became the overwhelmingly most important. In the same population, the city of Malmö, SIEFFERT (1963) presented data concerning myocardial infarction. In comparison to arteriosclerosis of the lower limb the incidence of myocardial infarction during an overlapping period of time did not increase appreciably. The two manifestations of arteriosclerotic disease obviously did not develop at the same rate in the population. HIRSCHMAN (1953) demonstrated that during the Second World War, in Sweden, when the standard of living with regard to food supply was low, the incidence of arteriosclerosis in autopsies decreased. During the time covered by the present study the standard of living, no doubt, improved. This increased standard has except for dietary habits also changed the means of transportation. So have for instance private automobiles become nine times as common. In the meantime the hospital facilities of the city have remained largely unchanged and, in relation to the population, decreased. During the time covered by this study no curative treatment of arteriosclerosis was introduced.

Similar changes are taking place or will take place in other communities

## DISCUSSION

### METHOD

The incidence of gangrene in diabetics and non-diabetics was calculated by BELL (1950) and based on more than 40,000 *autopsy* records covering the years 1920—1947. This study has later been followed up and the same type of data presented for 1948—1955 (BELL 1957).

Also it has been demonstrated that peripheral vascular disease in the legs is becoming an increasingly common cause of *amputation* (ENGSGARUP 1963, LINDHOLM 1964 and HANSSON 1964).

A good portion of these patients were diabetics and the incidence of *peripheral vascular complications in diabetes* has been investigated by RABINOWITZ et al. (1934), DRY and HINES (1941), BÜRGER (1951), McLAUGHLIN and HEIDER (1955), MELLINGHOFF (1955), SCHNEEWEISS and GASSMAN (1955), BUSCHMANN et al. (1958), KRAMER and PERILSTFIN (1958), BUGÁR-MÉSZÁROS and BERECKZY (1966) and LINDAHL and BOLUND (1969).

WIDMER et al. (1964) found *arterial occlusion* in the legs in 11 out of 1,550 women and 64 out of 4,887 men in a study of cardio-vascular disease in 6,400 drug industry employees. The study included only individuals under the age of 65. It was noticed that out of 4,826 men without arterial occlusion not less than 23 % had symptoms such as coldness or paresthesia from the legs, although, out of the 64 men with occlusion 30 % were free of symptoms. Obviously, it is difficult to separate pathological conditions in the peripheral arteries from those occurring with age in a majority of the population. Most of the individuals affected remain free of symptoms. In a fraction of the population there are varying degrees of dysfunction and in some instances arterial occlusion results in gangrene and even death.

For the purpose of the present study *hospital admission* because of severe signs or symptoms of peripheral arterial insufficiency has been the criterion. In the continuum of severity of arterial disease hospital admission is usually indicated at a level of severity when the patient can no longer be managed ambulatorily. At this stage the *diagnosis is usually obvious*.

Systematic changes in the indications for hospital admission over the years could not be demonstrated. No new therapeutic measures have changed the indications for hospitalization. The attitude towards vascular surgery has been very restricted in Malmö. The number of hospital beds available decreased in relation to the population. The duration of each hospitalization did not increase.

These findings indicate indirectly that no major changes in the attitude towards hospitalization of these cases have taken place.

### ASPECTS ON ARTERIOSCLEROSIS

The most prominent finding in the present study was the increase in incidence of arteriosclerosis obliterans in the lower limb in men. In the same population STENBY (1968) found in autopsies that arteriosclerotic changes were observed earlier in life and also were more common in men than in women. In clinical material including cases amputated because of arterial insufficiency several investigators (CARVEY and GOLDOWSKY 1957, ALFFRAM and HOLMQUIST 1961, PERLOW 1962, GENSLER et al. 1965, MITTY and ALMEDA 1967, HAIMOVICI 1967) found that the diabetics constituted half or more of their respective cases. In the early years of the present study diabetes was the most important condition in the group of disease causing peripheral vascular insufficiency, but later on, arteriosclerosis became the overwhelmingly most important. In the same population, the city of Malmö, SIEVERS (1963) presented data concerning myocardial infarction. In comparison to arteriosclerosis of the lower limb the incidence of myocardial infarction during an overlapping period of time did not increase appreciably. The two manifestations of arteriosclerotic disease obviously did not develop at the same rate in the population. HENNING (1953) demonstrated that during the Second World War, in Sweden, when the standard of living with regard to food supply was low, the incidence of arteriosclerosis in autopsies decreased. During the time covered by the present study the standard of living, no doubt, improved. This increased standard has except for dietary habits also changed the means of transportation. So have for instance private automobiles become nine times as common. In the meantime the hospital facilities of the city have remained largely unchanged and, in relation to the population, decreased. During the time covered by this study no curative treatment of arteriosclerosis was introduced.

Similar changes are taking place or will take place in other communities

of the world. However, it is not possible to extrapolate from the data of the present study to other types of communities or into the future without great care.

## ASPECTS ON DIABETES MELLITUS

Studies on the incidence of diabetes mellitus from different parts of the world and by different authors have yielded varying results. SILVER (1958) found in a survey of 46 studies published between 1916 and 1953 a variation between 0,4 and 43 per thousand. The incidence found by Silver in an area in the southern part of Sweden was 5,1 per thousand. The Diabetes Survey Working Party (MALINS et al. 1962) found the incidence in England and Wales to be 6,4 per thousand. The same group found that about the same frequency of previously undetected diabetes could be diagnosed in such a survey. REMEIN (1959) surveying 64 similar studies also reported that the incidence of undetected diabetes was about the same as that of known, diagnosed disease. In cases with myocardial infarction SIEVERS (1963) found that in cases which also had diabetes mellitus the latter disease in about 15 % of the cases was undetected prior to the cardiac. In the present study not less than 20 % of the cases were undiagnosed until they had been admitted to hospital because of their vascular symptoms. Values of similar magnitude have been found by other authors (Table 12, p. 31). Against the background of the high incidence of undiagnosed diabetes in the population this number is not surprising. In addition, a stress condition such as myocardial infarction or onset of severe peripheral vascular symptoms may well provoke a latent diabetes in the patient.

The risk of peripheral vascular complication in patients with diabetes has been estimated to be 2—59 % depending on the sampling procedure (CONWAY and MEICHER 1942, BÜRGER 1954 and KRAMER and PERILSTEIN 1958). RABKIN and FIELD (1962) found that of all diabetic patients admitted to hospital about seven per cent were amputated or subjected to vascular surgery. WHITE (1956) found that out of over one thousand cases of juvenile diabetics who had survived for more than 20 years almost half eventually had developed aortic calcification and that 0,5 % had gangrene. In the present study very few of the cases could be classified as juvenile diabetics.

Data on age and sex specific incidence of diabetes in the city of Malmö are not available. However, SILVER (1958) calculated these data in an area of southern Sweden close to the city (Kristianstad), and there is at the present time no reason to believe that diabetes should have different

Fig 24

diabetics to become  
admitted to hospital  
because of peripheral  
arterial insufficiency.

patterns in Malmö and other towns in southern Sweden. A projection of the incidence of peripheral vascular complications in the lower limbs on the population of diabetics combining the data of Silwer and the present study demonstrated that for septuagenarians when diabetes was most common so was the incidence of peripheral vascular complications in the legs. However, there was a significant increase of the annual incidence of peripheral vascular complication in diabetics starting in the sixth decade and increasing throughout life (Figure 24). In fact, for octogenarians the annual risk for diabetics of being admitted to hospital because of peripheral vascular insufficiency was four to five per cent.

BELL (1950) found in an autopsy material that gangrene was 40 times more frequent in diabetics as compared to non-diabetics. In the present study the annual incidence of peripheral arterial insufficiency for quinquagenarians was increased by a factor of about 30 in diabetics as compared to the population at risk. For octogenarians the annual risk of peripheral arterial insufficiency in diabetics increases considerably but at the same time the risk of arteriosclerosis in the rest of the population increases even more, so that peripheral arterial insufficiency is only eight times as frequent in diabetics. The data of Bell were obtained before 1950. Since then, as demonstrated in the present study arteriosclerosis as the cause of peripheral arterial insufficiency has become considerably more common which may explain the discrepancy between the two studies.

of the world. However, it is not possible to extrapolate from the data of the present study to other types of communities or into the future without great care.

## ASPECTS ON DIABETES MELLITUS

Studies on the incidence of diabetes mellitus from different parts of the world and by different authors have yielded varying results. study, however, it was not possible to demonstrate any significant changes in incidence over the years. On the other hand, the patients were significantly older during the later part of the period covered by this study.

### SOCIO-ECONOMIC ASPECTS

McLAUGHLIN (1913), ROOT et al. (1955) and RABKIN and FIELD (1962) presented accounting figures on the costs of hospital care of cases with diabetes and vascular complications. Diabetes was found to be a comparatively expensive disease and particularly so when vascular disease leading to amputation complicated the condition. Also, comparatively many patients needed care in nursing homes or similar institutions after discharge from hospital. In the hospitals involved in the present study the budgeting system does not permit extraction of the cost for separate patients. Basing the calculations on the average daily cost of a hospital bed and changes in the costs of living, it could be demonstrated that, in Malmö, the tripling of the hospital demands by the group of patients described above was associated with an increase of the costs, corrected for changes in the costs of living, in departments for somatic disease by nine times and in departments for chronic somatic disease by eleven times.

Integration into units for the care of cases with peripheral vascular disease, both ambulatory and hospitalized, is probably a requirement for progress in this field. The costs involved are an additional argument for an evolution along these lines.

The true incidence of peripheral vascular complication to diabetes mellitus in the city was increased only in men. KRAMER and PERILSTEIN (1958) claimed that the risk of vascular complication to diabetes increased between 1920 and 1956. The findings of these authors should be seen against the background of the increased risk for diabetic vascular complications with increasing age and the increasing survival of diabetics over the years. In the present study there was no indication that diabetic men should have a longer survival than the women. It may well be that circulatory impairment caused by the microangiopathy of diabetes mellitus remained unchanged over the years while the increased risk for men to have peripheral vascular complications to their diabetes is due to an increased risk of arteriosclerosis in these patients.

### ASPECTS ON THROMBANGITIS OBLITERANS

WESSLER et al. (1960) expressed the opinion that thrombangitis obliterans, Buerger's disease, did not exist as a pathological entity. NIELSEN (1969), however, found histo-pathological evidence of thrombangitis obliterans in 28 out of 448 patients with peripheral vascular insufficiency in the legs. MOZES et al. (1970) suggest that young patients with ischemic symptoms from the legs may belong to three groups, one of young arteriosclerotics, one with thrombangitis obliterans and a third with a combination of the two. In the present study it could be demonstrated that the diagnosis of thrombangitis obliterans had been less used in the later part of the period. However, there is no doubt that the diagnosis constitutes a deviating group, as they are almost all men, significantly younger than any other diagnostic group and with a survival that differs from the rest of the material.

### ASPECTS ON ARTERIAL EMBOLISM

BELL (1950) found in autopsies arterial embolism in 0,14 %. In cases amputated because of peripheral arterial insufficiency the frequency of arterial embolism has been described to range from 4,5 to 9,8 % (DALE and JACOBS 1962, PERLOW 1962, HANSSON 1964 and LINDHOLM 1964). In the present study the incidence of arterial embolism was no less than 10 %. THOMPSON et al. (1970) claimed that the disease indeed increased not only because of increasing age but also because of improvements in the treatment of patients with cardiac failure. In the present

study, however, it was not possible to demonstrate any significant changes in incidence over the years. On the other hand, the patients were significantly older during the later part of the period covered by this study.

## SOCIO ECONOMIC ASPECTS

McLAUGHLIN (1913), ROOT et al. (1955) and RANKIN and FIELD (1962) presented accounting figures on the costs of hospital care of cases with diabetes and vascular complications. Diabetes was found to be a comparatively expensive disease and particularly so when vascular disease leading to amputation complicated the condition. Also, comparatively many patients needed care in nursing homes or similar institutions after discharge from hospital. In the hospitals involved in the present study the budgeting system does not permit extraction of the cost for separate patients. Basing the calculations on the average daily cost of a hospital bed and changes in the costs of living, it could be demonstrated that, in Malmö, the tripling of the hospital demands by the group of patients described above was associated with an increase of the costs, corrected for changes in the costs of living, in departments for somatic disease by nine times and in departments for chronic somatic disease by eleven times.

Integration into units for the care of cases with peripheral vascular disease, both ambulatory and hospitalized, is probably a requirement for progress in this field. The costs involved are an additional argument for an evolution along these lines.

## SUMMARY AND CONCLUSIONS

A retrospective study was carried out on all individuals who had been admitted to hospital in the city of Malmö during the years 1949—1965 because of peripheral arterial insufficiency in their legs. The patients were classified in four main groups according to diagnosis: arteriosclerosis obliterans, diabetes mellitus, thrombangitis obliterans and arterial embolism. During this period 967 cases were admitted to hospital for the first time and from observations on these patients the following conclusions were made:

Women with arteriosclerosis obliterans were on the average eight years older than men and seven years older than men or women with diabetes mellitus. The age at first hospital admission of women with arteriosclerosis obliterans increased during the period covered by the study and this was also demonstrated for patients with arterial embolism.

The incidence of peripheral arterial insufficiency due to arteriosclerosis and diabetes mellitus in men increased over the years, and the increase could only to some extent be explained by changes in age distribution in the population.

Thrombangitis obliterans had been diagnosed less frequently in the later part of the period.

In the present study no preponderance for left or right could be proved. However, if the findings in other studies were taken into consideration it could be suspected that there is a preponderance for the left leg.

Bilateral involvement at the first admission was about 50 % more common in arteriosclerotics than in diabetics.

Most of the hospital admissions because of symptoms from the contralateral side took place within the first three years, and were more frequent in diabetics.

There was a decreased incidence of admission to hospital in late spring and summer with a peak value in the fall, and a true seasonal variation of these conditions could not be ruled out.

Women with arteriosclerosis obliterans had a shorter life expectancy than men with the same disease and died often shortly after the first admission. There was no difference in diabetics in this respect.

sclerotic men had a longer survival than diabetic men but arteriosclerotic women had a shorter survival than diabetic women.

Patients with arterial embolism had a poor life expectancy.

Individuals with diabetes and vascular complications in the lower limbs had been older at the time of the diagnosis of diabetes than is usually found in a non-selected material of this disease. Vascular complications to juvenile diabetes were rare.

In 20 % of the cases with diabetes mellitus this diagnosis had not been known prior to the first admission for vascular complication. The average time interval between the diagnosis of diabetes and the first admission was about 10 years and significantly shorter for women.

Altogether 2,243 hospital admissions of 1,056 patients with peripheral arterial insufficiency were used for the calculation of the demand of this group of patients on the hospital facilities in the city.

The men stayed for each admission in hospital somewhat longer than women, i.e. if they were admitted to the somatic departments but not to the Chronic Somatic Department. Patients with diabetes needed longer hospitalization than arteriosclerotics.

When the patients were discharged from their first admission about half could return to their homes and the rest had to use other hospital or nursing facilities except for one fifth who died. Arteriosclerotic women could less frequently than other groups return to their homes and also died more frequently.

The annual hospital days consumed by these patients in the city increased from about 4,000 in 1919 to about 14,000 in 1965. For the four groups the increase was proportionate to the changes in incidence.

## SUMMARY AND CONCLUSIONS

A retrospective study was carried out on all individuals who had been admitted to hospital in the city of Malmö during the years 1949—1965 because of peripheral arterial insufficiency in their legs. The patients were classified in four main groups according to diagnosis: arteriosclerosis obliterans, diabetes mellitus, thrombangitis obliterans and arterial embolism. During this period 967 cases were admitted to hospital for the first time and from observations on these patients the following conclusions were made:

Women with arteriosclerosis obliterans were on the average eight years older than men and seven years older than men or women with diabetes mellitus. The age at first hospital admission of women with arteriosclerosis obliterans increased during the period covered by the study and this was also demonstrated for patients with arterial embolism.

The incidence of peripheral arterial insufficiency due to arteriosclerosis and diabetes mellitus in men increased over the years, and the increase could only to some extent be explained by changes in age distribution in the population.

Thrombangitis obliterans had been diagnosed less frequently in the later part of the period.

In the present study no preponderance for left or right could be proved. However, if the findings in other studies were taken into consideration it could be suspected that there is a preponderance for the left leg.

Bilateral involvement at the first admission was about 50 % more common in arteriosclerotics than in diabetics.

Most of the hospital admissions because of symptoms from the contralateral side took place within the first three years, and were more frequent in diabetics.

There was a decreased incidence of admission to hospital in late spring and summer with a peak value in the fall, and a true seasonal variation of these conditions could not be ruled out.

Women with arteriosclerosis obliterans had a shorter life expectancy than men with the same disease and died often shortly after the first admission. There was no difference in diabetics in this respect. Arterio-

sclerotic men had a longer survival than diabetic men but arteriosclerotic women had a shorter survival than diabetic women.

Patients with arterial embolism had a poor life expectancy.

Individuals with diabetes and vascular complications in the lower limbs had been older at the time of the diagnosis of diabetes than is usually found in a non-selected material of this disease. Vascular complications to juvenile diabetes were rare.

In 20 % of the cases with diabetes mellitus this diagnosis had not been known prior to the first admission for vascular complication. The average time interval between the diagnosis of diabetes and the first admission was about 10 years and significantly shorter for women.

Altogether 2,243 hospital admissions of 1,056 patients with peripheral arterial insufficiency were used for the calculation of the demand of this group of patients on the hospital facilities in the city.

The men stayed for each admission in hospital somewhat longer than women, i.e. if they were admitted to the somatic departments but not to the Chronic Somatic Department. Patients with diabetes needed longer hospitalization than arteriosclerotics.

When the patients were discharged from their first admission about half could return to their homes and the rest had to use other hospital or nursing facilities except for one fifth who died. Arteriosclerotic women could less frequently than other groups return to their homes and also died more frequently.

The annual hospital days consumed by these patients in the city increased from about 4,000 in 1919 to about 14,000 in 1965. For the four groups the increase was proportionate to the changes in incidence.

## PREFACE

During my residency training 1966—1970 at the University of Vermont, Burlington, Vermont, the extent to which engineering principles could be applied to orthopaedic surgery became increasingly evident. This relationship was further emphasized by contacts with Professors Victor Frankel and Albert Burstein. Because of my engineering-oriented background I felt a strong desire to become more acquainted with this field by undertaking a biomechanical research study.

Following discussions with Professor and Chairman Frank Hoaglund it was recommended that I seek a biomechanical research fellowship with Professor Carl Hirsch, Chairman of the Department of Orthopaedics, Karolinska Hospital, Stockholm, Sweden. Due to his renowned reputation for basic research in this field, it was anticipated that I would obtain the best indoctrination possible in the experimental approach and measuring techniques necessary for biomechanical studies.

Shortly afterwards the author was challenged one morning on rounds by visiting Professor Arthur Hodgson from Hong Kong concerning the efficacy of weight-bearing braces. A preliminary search of the literature re-

vealed an astonishing lack of quantitative data to answer this question. It was then that the idea to design a method for quantitating forces between the leg and brace occurred. Further discussions with Dr Richard McLay of the Mechanical Engineering Department of the University of Vermont confirmed the feasibility of such a project.

Later the same year Professor Hirsch visited the University of Vermont and the idea was presented to him. He immediately recognized the possibilities and extended an invitation for me to come to Sweden and pursue the work.

Largely through the interest and support of Drs Frank Hoaglund, John Frymoyer, Phil Davis and other members of the Department of Orthopaedic Surgery at the University of Vermont, financial arrangements were made to help defray my fellowship expenses.

The major part of this work was done in collaboration with the Instrumentation Department of The Aeronautical Research Institute of Sweden. Their expertise in the use of instrumentation techniques was well utilized in solving the measuring problems

## INTRODUCTION

Many affections of the lower extremity are treated and protected in orthotic appliances. In the United States the ratio of prosthetic to orthotic needs is 10/1 (Rehabilitation Engineering 1971). The field of orthotics has not kept abreast with the advances in prosthetics and technology. It has only been within the past 10 years that significant results from orthotic research efforts have begun to emerge.

Despite the number of orthotic devices prescribed, the manner of formulating an orthotic prescription and selecting the appropriate device is ill-defined (McCollough, 1970). To merely state the need for an appliance is insufficient. The physician involved must be able to establish the biomechanical aspects of his patient's disability and then use them to translate his medical objectives into specific orthotic objectives. Finally he is faced with the problem of filling the prescription from a bewildering array of manufactured appliances which are poorly classified as to their specifications and indications (Henderson & Lamoreaux, 1969; Murdoch, 1970). It is no wonder that controversy exists over the functions a given brace can perform and that different prescrip-

tions are written for the same problem.

Appliances are assumed to perform functions for which they are unqualified while their detrimental effects remain either unknown or unheeded. The traditional ambulatory treatment of Legg-Perthe's disease in an ischial weight-bearing brace presupposes that loads on the affected femoral head will be diminished (Glimcher et al., 1970). In fact, the additional forces needed to accelerate or decelerate the braced limb by muscles spanning the diseased joint exceed body weight (Frankel and Burstein, 1970). The assumption that femoral fractures treated in weight-bearing cast braces can be effectively unloaded has been seriously challenged by Mooney et al. (1970). That the fractures heal may in fact be more related to the amount of loading which does occur because of the brace's ineffectiveness.

Braces which span joints limit their normal intersegmental motions in the transverse, frontal and sagittal planes (Viel, 1968). These motions act to conserve energy requirements by facilitating the interchange of potential and kinetic energy and reducing center of gravity excursions (Inman, 1968). A

of this test brace. I am most grateful to Department Head Knut Fristedt for his help in evolving the final brace design after many discussions and interchange of ideas. Through him I have learned valuable concepts about various instrumentation techniques. Electronics engineer Lennart Magnusson maintained the recording equipment in an operational status and offered many practical suggestions during our close association in the gait laboratory.

Ragnar Ranveg, Head of The Prosthetics-Orthotics Workshop, Department of Orthopaedic Surgery, Karolinska Hospital, and his staff did a fine job in constructing the plaster positive of my leg, the plastic laminated thigh shells and the shoe components.

My appreciation is extended to the visiting biomechanical engineers, Leon Kazarian, Albert Schultz and also Bo Klasson, Head, Prosthetic Research Laboratory Norrbacka Institute, for

their stimulating criticisms of the engineering aspects of this study; and to Drs John Kenwright and Manhar Patel for their clinical discussions.

I also wish to thank Lennart Jansson for the photography, Ingrid Ledström for help with administrative details, Vivian Kenwright for help with data reduction and Kerstin Sanfridson for typing assistance.

This project was supported by:

- 1 The State Medical Research Council (Grant: Hirsch, B71-17x-565-07 and B72-17x-565-08).

## INTRODUCTION

Many affections of the lower extremity are treated and protected in orthotic appliances. In the United States the ratio of prosthetic to orthotic needs is 10/1 (Rehabilitation Engineering 1971). The field of orthotics has not kept abreast with the advances in prosthetics and technology. It has only been within the past 10 years that significant results from orthotic research efforts have begun to emerge.

Despite the number of orthotic devices prescribed, the manner of formulating an orthotic prescription and selecting the appropriate device is ill-defined (McCollough, 1970). To merely state the need for an appliance is insufficient. The physician involved must be able to establish the biomechanical aspects of his patient's disability and then use them to translate his medical objectives into specific orthotic objectives. Finally he is faced with the problem of filling the prescription from a bewildering array of manufactured appliances which are poorly classified as to their specifications and indications (Henderson & Lamoreaux, 1969, Murdoch, 1970). It is no wonder that controversy exists over the functions a given brace can perform and that different prescrip-

tions are written for the same problem.

Appliances are assumed to perform functions for which they are unqualified while their detrimental effects remain either unknown or unheeded. The traditional ambulatory treatment of Legg-Perthe's disease in an ischial weight-bearing brace presupposes that loads on the affected femoral head will be diminished (Glimcher et al., 1970). In fact, the additional forces needed to accelerate or decelerate the braced limb by muscles spanning the diseased joint exceed body weight (Frankel and Burstein, 1970). The assumption that femoral fractures treated in weight-bearing cast braces can be effectively unloaded has been seriously challenged by Mooney et al. (1970). That the fractures heal may in fact be more related to the amount of loading which does occur because of the brace's ineffectiveness.

Braces which span joints limit their normal intersegmental motions in the transverse, frontal and sagittal planes (Viel, 1968). These motions act to conserve energy requirements by facilitating the interchange of potential and kinetic energy and reducing center of gravity excursions (Inman, 1968). A

of this test brace. I am most grateful to Department Head Knut Fristedt for his help in evolving the final brace design after many discussions and interchange of ideas. Through him I have learned valuable concepts about various instrumentation techniques. Electronics engineer Lennart Magnusson maintained the recording equipment in an operational status and offered many practical suggestions during our close association in the gait laboratory.

Ragnar Ranveg, Head of The Prosthetics-Orthotics Workshop, Department of Orthopaedic Surgery, Karolinska Hospital, and his staff did a fine job in constructing the plaster positive of my leg, the plastic laminated thigh shells and the shoe components.

My appreciation is extended to the visiting biomechanical engineers, Leon Kazarian, Albert Schultz and also Bo Klasson, Head, Prosthetic Research Laboratory Norrbacka Institute, for

their stimulating criticisms of the engineering aspects of this study; and to Drs John Kenwright and Manhar Patel for their clinical discussions.

I also wish to thank Lennart Jansson for the photography, Ingrid Ledström for help with administrative details, Vivian Kenwright for help with data reduction and Kerstin Sanfridson for typing assistance.

## INTRODUCTION

Many affections of the lower extremity are treated and protected in orthotic appliances. In the United States the ratio of prosthetic to orthotic needs is 10/1 (Rehabilitation Engineering 1971). The field of orthotics has not kept abreast with the advances in prosthetics and technology. It has only been within the past 10 years that significant results from orthotic research efforts have begun to emerge.

Despite the number of orthotic devices prescribed, the manner of formulating an orthotic prescription and selecting the appropriate device is ill-defined (McCollough, 1970). To merely state the need for an appliance is insufficient. The physician involved must be able to establish the biomechanical aspects of his patient's disability and then use them to translate his medical objectives into specific orthotic objectives. Finally he is faced with the problem of filling the prescription from a bewildering array of manufactured appliances which are poorly classified as to their specifications and indications (Henderson & Lamoreaux, 1969, Murdoch, 1970). It is no wonder that controversy exists over the functions a given brace can perform and that different prescrip-

tions are written for the same problem.

Appliances are assumed to perform functions for which they are unqualified while their detrimental effects remain either unknown or unheeded. The traditional ambulatory treatment of Legg-Perthe's disease in an ischial weight-bearing brace presupposes that loads on the affected femoral head will be diminished (Glimcher et al, 1970). In fact, the additional forces needed to accelerate or decelerate the braced limb by muscles spanning the diseased joint exceed body weight (Frankel and Burstein, 1970). The assumption that femoral fractures treated in weight-bearing cast braces can be effectively unloaded has been seriously challenged by Mooney et al. (1970). That the fractures heal may in fact be more related to the amount of loading which does occur because of the brace's ineffectiveness.

Braces which span joints limit their normal intersegmental motions in the transverse, frontal and sagittal planes (Viel, 1968). These motions act to conserve energy requirements by facilitating the interchange of potential and kinetic energy and reducing center of gravity excursions (Inman, 1968). A

locked knee increases the total energy cost by up to 25% (Viel, 1968; Inman, 1968). Malalignment of brace joints produces excessive wear on the appliance and potentially detrimental effects on the patient (Lechlitner, 1966; von Werssowetz, 1962).

Research in the field of lower extremity orthotics today is hampered by the lack of quantitative clinical data, no standardized means of acquiring this clinical data and the inability to correlate clinical findings with a particular brace. Consequently long range response predictions to orthoses can only be speculated. (Lehmann et al., 1970.)

Brace research and development is mostly based on past experience and clinical observations which results in overdesign; excessive safety margins, increase in weight and bulk (Lehneis, 1969). In order to develop an optimal brace configuration clinical evaluation must be supplemented with biomechanical analysis. This combined approach provides a broader insight into the dynamic behavioral characteristics of the leg-brace system, and enables responses to be predicted for which no directly applicable empirical data is available. Design and modification can then be accomplished with more confidence that the desired clinical result will be obtained.

### **Approach to the problem**

Biomechanical analysis of lower extremity braces can be approached in several ways. One is to instrument and study standard appliances. This

method is easier but limited in the information obtained because of the susceptibility of such flexible systems to large cross-sensitivity errors. Another approach and the one taken by the author is to design a test brace, simulate selected prescriptions and study force-time histories. This comprehensive approach helps to define broader force envelopes, yield more realistic response predictions, provide a greater understanding of the biomechanical nature of the interacting systems, facilitate the correlation of physiological and psychological responses with mechanical input and enable a more scientific approach to brace design.

### **Purpose and objectives**

The purpose of this project was to study the interactions between the brace and leg by the analysis of force-time histories recorded from selected ischial weight-bearing brace combinations.

The project was divided into two basic parts:

- I. The design of a test brace, compatible instrumentation and reliable data acquisition and analysis techniques
- II The application of the test equipment and methods to a general investigation on selected ischial weight-bearing brace combinations

Specific information was sought about the following:

1. The magnitude of forces and moments to which specific brace structures and the leg are subjected.
2. The magnitude and distribution of loading which occurs on the brace with different thigh shell configurations.
3. The degree of weight relief (or skeletal unloading) experienced by the leg with different brace combinations as a function of:
  - a) the anterior wall in the seat shell and maintainance of ischial seat contact
  - b) patten bottom vs. shoe attachments
  - c) fixed and hinged ankle joints
4. The significance of the joint hinge location on calf band force patterns
  - a) heel hinge
  - b) ankle hinge
5. The effect of foot alignment on the calf band force patterns
  - a) free ankle; internal, neutral, external rotation
  - b) fixed ankle; dorsiflexion, neutral, plantarflexion
6. Rotational and angulatory stability imparted to the extremity within the thigh shell.
7. Brace loading caused by muscle forces
8. Alteration of the gait pattern expressed in terms of the contact duration of each foot position and the timing of force maximums.

locked knee increases the total energy cost by up to 25% (Viel, 1968; Inman, 1968). Malalignment of brace joints produces excessive wear on the appliance and potentially detrimental effects on the patient (Lechlitner, 1966; von Werssowetz, 1962).

Research in the field of lower extremity orthotics today is hampered by the lack of quantitative clinical data, no standardized means of acquiring this clinical data and the inability to correlate clinical findings with a particular brace. Consequently long range response predictions to orthoses can only be speculated. (Lehmann et al., 1970.)

Brace research and development is mostly based on past experience and clinical observations which results in overdesign; excessive safety margins, increase in weight and bulk (Lehneis, 1969). In order to develop an optimal brace configuration clinical evaluation must be supplemented with biomechanical analysis. This combined approach provides a broader insight into the dynamic behavioral characteristics of the leg-brace system, and enables responses to be predicted for which no directly applicable empirical data is available. *Design and modification* can then be accomplished with more confidence that the desired clinical result will be obtained.

### Approach to the problem

Biomechanical analysis of lower extremity braces can be approached in several ways. One is to instrument and study standard appliances. This

method is easier but limited in the information obtained because of the susceptibility of such flexible systems to large cross-sensitivity errors. Another approach and the one taken by the author is to design a test brace, simulate selected prescriptions and study force-time histories. This comprehensive approach helps to define broader force envelopes, yield more realistic response predictions, provide a greater understanding of the biomechanical nature of the interacting systems, facilitate the correlation of physiological and psychological responses with mechanical input and enable a more scientific approach to brace design.

### Purpose and objectives

The purpose of this project was to study the interactions between the brace and leg by the analysis of force-time histories recorded from selected ischial weight-bearing brace combinations.

The project was divided into two basic parts:

- I. The design of a test brace, compatible instrumentation and reliable data acquisition and analysis techniques.
- II. The application of the test equipment and methods to a general investigation on selected ischial weight-bearing brace combinations.

Specific information was sought about the following:

knee are currently under evaluation (Staros, 1971)

Several authors have reported encouraging results using cast and conventional braces for the early ambulatory treatment of fractures (Mooney and Harvey, 1970) and delayed union (Werner, 1969). Because of the array of brace components available from different manufacturers with no standard classification system, Staros (1971) has suggested a system of component classification based on whether the device prevents, limits, resists or permits joint motion

McCollough et al (1970) has described a systematic approach to orthotic prescription which should help to standardize terminology and facilitate a more accurate assessment of the disability

By contrast to these numerous, diversely oriented and qualitative approaches to orthotic research, quantitative studies devoted to force measurements are limited (Prosthetics and Orthotics, 1967).

Glimcher (1950) reported stress analysis studies conducted on an instrumented long-leg brace. Strain gages mounted on the medial upright and horizontal bands were used to study the effect of strap tightening and ambulation. However, applied forces could not be directly measured because of cross-sensitivity difficulties

Desai and Henderson (1961) designed a short-leg brace with a double axis ankle which permitted both ankle and subtalar motion.

Staros and Peizer (1965) evaluated the unweighting effectiveness of the

Veterans Administration Prosthetics Center Below-Knee, Weight-Bearing Brace by simultaneously measuring an instrumented stirrup assembly and force plate output signals. Maximal unweighting occurred at heel strike and was different on the right and left sides

Hodge (1967) statically loaded an instrumented aluminum ischial weight-bearing brace which was mounted in a jig. Loads up to 250 lbs were applied and stresses from lateral deflections at the ankle and knee levels were computed. He considered this type of loading more conducive to structural failure than axial loads. From the stresses calculated aluminum was considered a suitable material for weight-bearing braces.

Magora et al. (1968) and Robin et al (1968) instrumented lower leg drop-foot braces and computed stresses from recorded strain output signals using different gait patterns on a normal subject. Stress patterns indicated that posterior spring-type braces were more susceptible to fatigue failure

A series of biomechanical studies have been conducted at the University of Washington, Seattle in conjunction with the Departments of Mechanical Engineering and Physical Medicine and Rehabilitation (Kirkpatrick et al., 1969, Lehmann et al., 1969 and 1970).

By using sophisticated data acquisition and analysis techniques, instrumented brace and floor reaction output signals are synchronized, digitized, interfaced with a computer and subsequently printed out in the form of fully integrated force-time histories

## SURVEY OF THE LITERATURE

Organized research efforts in the field of lower extremity orthotics did not appear until 1956 when the experience gained in prosthetics from working with veteran amputees was found also applicable to the allied field of orthotics (Wilson, 1963).

The main stream of lower extremity orthotic research has been oriented toward qualitative improvements in design, wider application to more acute problems such as fracture treatment and administrative efforts to systematize orthotic prescription, component classification and prefabrication (Staros, 1971). Several recent and detailed reviews cover the current trends in orthotics (Lehneis, 1969; Lehmann, et al., 1970; Report of Seventh Workshop Panel, 1970). A representative survey is presented to distinguish this type of research from the quantitatively oriented nature of biomechanical force-measurement studies (Braces, Splints and Assistive Devices, 1969; Cochran, 1971).

Anderson and Bray (1964) and Strohm et al. (1966) reported a functional long-leg brace designed to permit ambulation without knee locks. Grynbaum et al. (1969) reported an adjustable ischial weight-bearing brace

which featured an inflatable anterior wall lining to maintain a snug fit and reduce the number of brace sizes required in stock. Russek (1958) attached a wood quadrilateral socket to the proximal end of an ischial weight-bearing brace to provide better support. Recognizing that hip joint forces developed during ambulation often exceed body weight, and that this was partly due to the abductor muscle group activity, Glimcher et al. (1970), are developing an ischial weight-bearing brace used for the treatment of Legg-Perthe's disease which requires the patient to balance on the end of a single medial upright without any leg fixation thus keeping the abductor muscle group inactive.

Plastic materials which are lighter than steel or aluminum and cosmetically more appealing are being utilized in below knee orthoses such as the spiral helix drop-foot brace (Fifth Workshop Panel on Lower Extremity Orthotics) and corrugated polypropylene versions of different below and above knee orthoses (Engen, 1970). Attempts have been made to more closely follow anatomic joint motion. Polycentric joint designs which simulate the multiplanar motion of the

knee are currently under evaluation (Staros, 1971).

Several authors have reported encouraging results using cast and conventional braces for the early ambulatory treatment of fractures (Mooney and Harvey, 1970) and delayed union (Werner, 1969). Because of the array of brace components available from different manufacturers with no standard classification system, Staros (1971) has suggested a system of component classification based on whether the device prevents, limits, resists or permits joint motion.

McCollough et al (1970) has described a systematic approach to orthotic prescription which should help to standardize terminology and facilitate a more accurate assessment of the disability.

By contrast to these numerous, diversely oriented and qualitative approaches to orthotic research, quantitative studies devoted to force measurements are limited (Prosthetics and Orthotics, 1967).

Glimcher (1950) reported stress analysis studies conducted on an instrumented long-leg brace. Strain gages mounted on the medial upright and horizontal bands were used to study the effects of strap tightening and ambulation. However, applied forces could not be directly measured because of cross-sensitivity difficulties.

Desai and Henderson (1961) designed a short-leg brace with a double axis ankle which permitted both ankle and subtalar motion.

Staros and Peizer (1965) evaluated the unweighting effectiveness of the

Veterans Administration Prosthetics Center Below-Knee, Weight-Bearing Brace by simultaneously measuring an instrumented stirrup assembly and force plate output signals. Maximal unweighting occurred at heel strike and was different on the right and left sides.

Hodge (1967) statically loaded an instrumented aluminum ischial weight-bearing brace which was mounted in a jig. Loads up to 250 lbs were applied and stresses from lateral deflections at the ankle and knee levels were computed. He considered this type of loading more conducive to structural failure than axial loads. From the stresses calculated aluminum was considered a suitable material for weight-bearing braces.

Magora et al. (1968) and Robin et al. (1968) instrumented lower leg drop-foot braces and computed stresses from recorded strain output signals using different gait patterns on a normal subject. Stress patterns indicated that posterior spring-type braces were more susceptible to fatigue failure.

A series of biomechanical studies have been conducted at the University of Washington, Seattle in conjunction with the Departments of Mechanical Engineering and Physical Medicine and Rehabilitation (Kirkpatrick et al., 1969, Lehmann et al., 1969 and 1970).

By using sophisticated data acquisition and analysis techniques, instrumented brace and floor reaction output signals are synchronized, digitized, interfaced with a computer and subsequently printed out in the form of fully integrated force-time histories.

by a Calcomp plotter. This measuring technique has facilitated a series of force-measurement studies on the performance characteristics of standard braces.

From these studies the unloading effectiveness of ischial weight-bearing braces has been seriously challenged. Optimal effectiveness was found with a quadrilateral thigh shell, fixed ankle, metal sole plate extending to the metatarsal heads, rocker bottom attachment and skilfull loading by the wearer.

The effect of different instrumented below knee braces on knee stability

was evaluated by measuring calf band forces exerted against the leg. The forces cause knee flexion and extension moments which substantiates quantitatively what has been known clinically about the effect of heel and toe lever arms.

Mooney and Harvey (1970) investigated the weight-bearing properties of total contact cast braces used for recent femoral and tibial plateau fractures. Static comparisons between forces at the knee and floor showed unloading to be inversely proportional to body weight. Dynamic studies were not conducted.

## INSTRUMENTATION AND TEST PROCEDURE

### The Design of a Measuring System

In order to design and construct a functional test brace, compatible instrumentation and related equipment the Instrumentation Dept of the Aeronautical Research Institute of Sweden and the Prosthetic-Orthotic Workshop of the Dept of Orthopedic surgery, Karolinska Hospital, Stockholm, were consulted. Throughout the project it was necessary to maintain a close working relationship with the two disciplines.

The primary objective was to measure forces during ambulation exerted on the leg-brace interfaces. These forces arise from a combination of muscular activity, body weight, inertial and ground reactions. The method used in principle was to attach representative brace interfaces to the leg and study the resulting dynamic interactions.

In practice this was accomplished by fastening the interfaces to a measuring system which was mounted on a frame of sufficient stiffness to prevent mutual interactions between the interface segments. A typical ischial weight-bearing brace is attached to the leg by essentially four segments which have the following functions:

1. ischial seat platform, lateral and anterior walls: provide weight bearing and rotational control
2. corset: provides alignment and partial weight bearing
3. calf band: provides alignment but no weight bearing
4. foot assembly: provides alignment and foundation for the brace structure.

A study of individual forces acting on each contacting segment will yield a clearer picture of the overall performance at different levels.

The interactions between the leg and brace are represented by a combination of moments and forces. In order to have a statically determinate system it was necessary to convert the forces and moments into three orthogonal force components at three different points on the two upper brace rings corresponding to the seat and corset areas. This was achieved by using universal couplings between the leg-brace interface assemblies and the measuring system.

In the lower segment the calf transducers were aligned so as to record only the transverse plane components X and Z; and the ankle transducers

Figure 1 Positive plaster model and brace mockup under construction

only the brace long axis component  $Y$ . Fig. 17 c shows the orthogonal force component system.

The force components applied to each transducer were predicted from estimates based on a known body weight of 61kp acting vertically downward on a brace system undergoing maximal inclinations from the vertical of approximately 14 degrees. At the slightly slower than normal walking

speeds expected inertial forces were considered negligible.

Vertical floor reactions were correlated with the brace forces by utilizing the 5 meter electronic walkway (Rydell, 1966) in the gait laboratory of the Department of Orthopaedics, Karolinska Hospital. Since preliminary measurements, taken during ambulation, showed the maximal angle of the brace's long axis to be in the

sagittal plane, 14 degrees, and in the frontal plane, 5 degrees, conversion of floor reaction forces to the brace axis as described by Lehmann et al. (1970) was not considered necessary. The cosine of small angles approaches 1, and the difference is too small to justify more complicated photographic methods of angle measurement.

### Brace Construction

The design objective was to provide a structure of sufficient stiffness to prevent interactions from occurring between the leg-brace interface assemblies. Following the preliminary discussions, a positive plaster of paris model of the author's left leg was prepared (Fig. 1). This served as a basis on which to construct a wood mockup of the initial brace assembly, to locate the longitudinal structures and cross sections, to limit column length and determine the locations of transducer placement

Early in the study it was concluded that the basic assembly must be divided into an upper and lower segment in order to facilitate entry and egress

Construction material was:

Aluminum SM 6508 (weldable),

Svensk norm 515 4212-6

$E = 7000 \text{ kp/mm}^2$

$\sigma_c = 25 \text{ kp/mm}^2$

Each segment is constructed of circular ring sections and four longitudinal 10 mm solid tubular uprights (Fig. 2)

The individual segments were jigged, argon welded and mechanically fasten-

Figure 2. Complete brace without wiring. Couplings between the the upper and lower segments are seen above the stiffner plates.

ed to each other. In the completed assembly applied loads were transferred to the longitudinal members which were stabilized by the circular cross sections. Cutouts were kept to a minimum to maximize the brace's stiffness and reduce the bending and torsional deflections during loading. The assembled configuration is in the form of a truss made of Duraluminum which provides a high degree of struc-

Figure 3. Fully assembled brace with shells, calfband and cabling

Figure 4 Upper and lower segments uncoupled.

tural rigidity with minimum weight (Fig. 3 & 4).

Onto the basic structural assembly were welded eight uniaxial and parallel keyed telescoping fixtures which provided a means of securely mounting, adjusting and locking the seat, corset and foot-ankle assemblies. The strain gage transducer bodies were mechanically fitted onto the telescoping fixtures and served as a mount to interface the sensing elements with the seat and corset and foot-ankle assemblies

### Transducers

The basic principle underlying the design of the transducers was that moments applied to a beam on which sensing elements are mounted produce greater strains per given force than direct compressive or tensile forces.

Six transducer bodies support the thigh segments and convert via universal couplings the forces and moments transmitted from the leg to the brace into six different reaction forces. Each transducer body has the ability to resolve its own force into three ortho-

gonal components. The geometry of the force transducers allowed each force component to exert its own moment upon a strain gage bridge situated where the cross sectional area had been chosen to give a suitable strain for the predicted loads. The same bending beam principle was used to design the calf and ankle transducers. The ankle transducers were aligned to measure only the brace's long axis component (Y) and the calf transducers were aligned to measure only the transverse plane components (X & Z).

Transducer bodies were constructed from BOFORS RD-653 steel Svensk Norm 515 2225-5

$$E = 21,000 \text{ kp/mm}^2$$

$$\sigma_{11} = 70 \text{ kp/mm}^2$$

This material was chosen because of its high yield strength and the fact that steel is a good base material for strain gage bonding. Micro-Measurement foil gages were bonded with an epoxy cement and then heat treated. Details of construction and strain gage locations are shown for the upper segment in Fig 5 a & b, and for the lower segment in Fig 6 & 7.

Figure 5a. Typical upper segment transducer showing mounted foil strain gages and universal coupling

BLUE PRINT OF TYPICAL  
UPPER SEGMENT TRANSDUCER

Figure 5 b Dimensions are in mm

The calf transducer bodies consist of two beams 76 mm long, 12 mm wide and 3 mm thick bolted to the anterior and lateral aspect of the middle ring of the lower segment (Fig. 7 & 12). Connection between the calf band and the transducer bodies was established by an adjustable system of bolts and locknuts. Only the force components along the X and Z axis were measured at this level since the calf band has no weight-bearing function.

The ankle transducers were constructed using a ring design in order to measure only the force component along the Y axis. Because the transducer bodies also functioned as a coupling between the brace and foot assembly, it was desirable to maintain the distance separating them as small as possible. This was accomplished by using a flattened circle configuration (Fig. 6 & 7).

### Interface Assemblies

Interface assemblies are composed of contour-fitted plastic shells, mounting rings and foot-ankle components.

The plastic contour shells act to transmit forces between the leg and brace and to assist in maintaining alignment within the brace.

The seat and corset were cut from a 3 mm thick basic thigh shell layed up on the plaster positive mold (Fig. 8). The shell was divided into two segments, an upper 1/3 seat shell and a lower 2/3 corset shell. The upper seat perimeter was anatomically contoured (Fig. 9). The anterior wall was

Figure 6 Ankle transducer without foot assembly

BLUE PRINT OF TYPICAL  
UPPER SEGMENT TRANSDUCER

Figure 5 b. Dimensions are in mm

The calf transducer bodies consist of two beams 76 mm long, 12 mm wide and 3 mm thick bolted to the anterior and lateral aspect of the middle ring of the lower segment (Fig 7 & 12) Connection between the calf band and the transducer bodies was established by an adjustable system of bolts and locknuts. Only the force components along the X and Z axis were measured at this level since the calf band has no weight-bearing function

The ankle transducers were constructed using a ring design in order to measure only the force component along the Y axis. Because the transducer bodies also functioned as a coupling between the brace and foot assembly, it was desirable to maintain the distance separating them as small as possible This was accomplished by using a flattened circle configuration (Fig. 6 & 7).

### Interface Assemblies

Interface assemblies are composed of contour-fitted plastic shells, mounting rings and foot-ankle components.

The plastic contour shells act to transmit forces between the leg and brace and to assist in maintaining alignment within the brace.

The seat and corset were cut from a 3 mm thick basic thigh shell layed up on the plaster positive mold (Fig. 8) The shell was divided into two segments, an upper 1/3 seat shell and a lower 2/3 corset shell The upper seat perimeter was anatomically contoured (Fig 9) The anterior wall was

Figure 6 Ankle transducer without foot assembly

Figure 7 Lower segment upside down showing the ankle transducers, calf band beam transducers and couplings for attachment to the upper segment.

Figure 5 b Dimensions are in mm

sectioned from one seat shell to access its importance in maintaining ischial contact. Corset shells were similarly divided. Entrance and egress was accomplished through anterior longitudinal seams held closed by Velcro fasteners. The shells were fastened to the seat and corset mounting rings by four steel angle iron brackets (Fig. 10 and 11).

The mounting rings serve as attachments for the body-brace interface components and the structure by which the whole assembly is connected to the transducers. They are circular 3 mm  $\times$  40 mm aluminum argon welded units. Fastened to the outer ring surface are mounting bolts in positions corresponding to the transducers on the main brace frame. Slots were cut to receive the shell mounting bracket bolts and permit adjustments in alignment.

surface of the sole and extended from the heel to the metatarsal heads to provide a rigid mounting platform for the stirrup and caliper attachments. To this plate were mechanically fastened the caliper or stirrup assemblies by means of an array of tapped holes which permitted different mounting positions. The rubber heel was fastened in place over the selected assembly (Fig. 13).

The caliper frame consisted of a 10 mm solid tubular aluminum U

shaped structure which was threaded at each end for insertion into the ankle transducer bodies. Alone, it functioned as a patten bottom. In conjunction with a channel iron fastened to the sole plate it functioned as a caliper with heel hinge (Fig. 14 and 15).

By attaching stiffener struts between the sole plate and caliper frame arms the ankle could be fixed in selected positions of dorsiflexion, neutral and plantarflexion (Fig. 15).

The stirrup assembly consisted of

Figure 12. Details of calfband and mounting position.

The calf band consisted of a circumferential plastic laminated layup, 3 mm thick and 70 mm high with a posterior-medial entry cut, mechanically fastened to the beam transducers by two bolts (Fig 12)

The shoe assembly was fabricated from a standard low cut oxford shoe with a leather sole and rubber heel. There were no orthopaedic modifications. A steel plate, 3 mm thick, was firmly riveted in place on the under

TOP VIEW RELATIVE ORIENTATION OF SEAT AND CORSET RING CENTERS

Figure 17 a

Figure 15. Shoe with caliper frame mounted in the channel iron and fixed by angle struts.

Figure 16. Shoe with stirrup assembly attached

a stainless steel U shaped base plate and two threaded mounting bolts connected by a box-type hinge. The base plate was fastened to the sole plate and the mounting bolts fastened to the ankle transducer bodies (Fig. 13 and 16).

The assembled brace lacks contouring and from a survey of ischial weight-bearing appliances in this institution, is 2—3 kg heavier. Weight without cabling is 5 kg (upper segment 3 kg, lower segment 2 kg with shoe) which was considered acceptable if the inertial forces from rapid extremity movements during gait were avoided.

There were no restrictions on leg movements other than would normally be expected in a standard long-leg brace.

### Alignment of Components

The leg with thigh shell applied was placed inside the brace frame, alignment adjusted and the sites of attachment to the interface assembly rings marked. The shell was then divided as previously described. A margin of 5 mm was left between apposing edges to prevent mutual contact. Sufficient mounting bolts, spacers and fillers were used to insure good fixation and uniform force transmission to the rings. In the standing position a plumbline passed from the middle of the ischial seat to the heel's midline and the shoe sole was flat on the floor. Fig 17a shows the relationship of the upper and lower measuring ring centers to each other.

## Foot Switch Circuit

The foot switch circuit consisted of metal tape, attached to the walkway plates and heels and soles of each shoe, connected across a DC power supply, three different resistors and a galvanometer in each recorder. A step pattern of different height for each foot position appeared on the recording (Fig. 25).

## Calibration

Calibration refers to the application of known loads along a specified axis of a measuring system and recording the output signals produced. From the established relationships, unknown forces applied to the system in the same direction can be quantitated. During calibration strains may be registered along axes other than the one loaded. This phenomenon is called cross sensitivity and is produced within the system by externally applied loads. The accuracy of the measurements and ability to define the applied forces requires that the cross sensitivity be small. Factors which increase cross sensitivity are related to improper transducer design, inexact mounting of the strain gages, and distortions of the mounting frame producing misorientation of the strain gages under loading.

Compared to standard braces which have been directly instrumented, the cross sensitivity error on this brace should be greatly reduced by the careful design, accurate alignment of strain gages and the rigid framework

on which the transducer's parallel alignment is maintained.

Individual transducers were calibrated statically in a jig by applying loads up to 4 kp along the X and Z axis and up to 14 kp along the Y axis (Fig. 23 a). Fig. 23 b shows typical calibration curves for one transducer. Cross sensitivity was less than 5%.

The upper and lower segments were separately jugged and loaded to access the accuracy of the integrated thigh, calf and ankle measuring systems (Fig. 24). The error was found to be 5%. The two segments were not coupled and calibrated as a unit because it was assumed that each segment's stiffness properties would preclude a significant effect from being introduced as a result of the connection.

Figure 23a An upper segment force transducer, jugged and undergoing calibration

## DATA REDUCTION AND ANALYSIS

### Manual reduction

Oscillograph recordings were inspected for calibration marks and then base-lines for all channels were drawn. Three steps in the middle of the walk closest in time duration and force pattern were segmented into foot position and force maximum intervals (Fig. 25).

Figure 25 Segmentation of a typical force curve for digital conversion using the foot switch recording

Superimposed tracings of the channels were then drawn to confirm their similarity and facilitate comparison with other walks. One step, closest to the average of the three, was converted into digital form at each interval. Using the numerical data, equations of equilibrium Fig. 26, the ring dimensions in Fig. 17b and the sign conventions in Fig. 17c, individual forces at the ring, calf band, and ankle units were summed and moments computed. Allowance was made for the slight offset between the corset ring center and seat ring center (Fig. 17a).

Walkway recordings were similarly segmented and digitized. Foot positions were converted to percentages of total stance phase time. The relationship of each force maximum was determined with respect to a specific foot position. Different runs and each run, braced and unbraced sides, were compared.

The profile used for further analysis of each walk consisted of three analog force tracings, summed forces and moments and the foot-position force-peak relationships.

## Test-Walking Procedure

Prior to conducting test walks, the recording equipment was allowed to warm up and then all brace and walkway channels were calibrated with a calibration resistor. The brace was applied over a single layer of stockinette and after sufficient walking to settle well into the thigh shell segments it was established that good contact existed between the ischium and seat platform by finger palpation (Orthopaedic Appliance Atlas, 1952) and that the heel was not in contact with the inner sole of the shoe.

The test walk was started two steps before contact with the walkway and ended two to three steps beyond the end of the walkway to minimize the effects of acceleration and deceleration on the force-time histories.

Walking speed was gaged to a previously established time reference from many averaged walks in the brace. This walking speed was about half the normal unbraced walking speed of the same subject. No test walk was accepted unless within 0.5 seconds of the 10 second reference and unaccompanied by accidental lurches, scrapes or scuffs.

The walk was observed by an orthopaedic surgeon, orthotist, the instrument technician and the author himself by means of a mirror situated at the far end of the walkway.

Adequate rest periods were taken between walks to eliminate fatigue variabilities on the gait pattern.

Figure 24. Assembled upper segment mounted in calibration jig. The seat ring is axially loaded to check the integrated system's response

## RESULTS

### General Interpretation

Data representing different brace variables listed in Table 1 was evaluated.

The walks can be divided into essentially three similar groups:

1. closed seat shell-closed corset
2. open seat shell-closed corset
3. closed seat shell-open corset

The first two groups were tested on the same day and the third group 9 days later. There were greater differences in the general results between the third and first two groups which is

attributed to diurnal variables previously discussed and the greater dynamic alignment changes permitted by the reduced corset area.

Since one of the major purposes of this project was to elicit broad force envelopes it was decided to pool all runs together and compute force means and ranges. Where interesting differences were noted further amplification is presented. Foot-assembly evaluations are compared on an individual basis.

Figures 17 b and 17 c show the in-

Table 1 Walks conducted in different brace combinations.

Walk number	Seat shell	Corset shell	Foot assembly
1	closed	closed	patten bottom

### Reliability of the equipment and experimental method

The overall error can be divided into instrumentation, manual reduction and experimental method errors. These are outlined below.

1. Instrumentation error
  - a) cross-sensitivity error  $\pm 3\%$
  - b) calibration error  $\pm 5\%$
  - c) recorder drift  $\pm 2\%$
  - d) recorder errors within the flat frequency range used  $\pm 2\%$
2. Manual reduction error  $\pm 3\%$
3. Variability in the experimental method  $\pm 5\%$

Apart from the brace performance, force variations between walks can occur from a change in body weight, fatigue, removal and application times for the apparatus, normal step to step and day to day diurnal differences in gait pattern. Appoldt & Bennett (1968)

$$\begin{aligned}x_A &= x_1 + x_2 + x_3 \\y_A &= y_1 + y_2 + y_3 \\z_A &= z_1 + z_2 + z_3 \\m_{x_A} &= b(y_3 - y_1) \\m_{y_A} &= b(x_3 - x_1) - a(z_1 + z_3) + c \cdot z_2 \\m_{z_A} &= c \cdot y_2 - k(y_1 + y_3)\end{aligned}$$

$$\begin{aligned}x_B &= x_4 + x_5 + x_6 \\y_B &= y_4 + y_5 + y_6 \\z_B &= z_4 + z_5 + z_6 \\m_{x_B} &= f(y_6 - y_4) \\m_{y_B} &= f(x_6 - x_4) - e \cdot z_5 + m(z_4 + z_6) \\m_{z_B} &= m(y_4 + y_6) - e \cdot y_5\end{aligned}$$

studied the effect of these variables during investigations of AK stump-socket pressures and found that they could cause a scatter of  $\pm 10\%$  about the mean values. This variability was minimized when test runs were conducted on the same day.

During this project the subject's weight remained constant at 61 kp, adequate rest periods were observed, the apparatus on and off time was never more than 15 minutes, most of the test runs were conducted on the same day and the remainder within the next 9 days. Because of these precautions the scatter effect is estimated to be less than 5%. It is unlikely that all errors will combine simultaneously in the same direction to produce an error as large as 20%. A realistic estimate of the measuring error is considered to be  $\pm 10\%$  (Hetenyi, 1963).

## RESULTS

### General Interpretation

Data representing different brace variables listed in Table 1 was evaluated.

The walks can be divided into essentially three similar groups:

- 1 closed seat shell-closed corset
2. open seat shell-closed corset
- 3 closed seat shell-open corset

The first two groups were tested on the same day and the third group 9 days later. There were greater differences in the general results between the third and first two groups which is

attributed to diurnal variables previously discussed and the greater dynamic alignment changes permitted by the reduced corset area.

Since one of the major purposes of this project was to elicit broad force envelopes it was decided to pool all runs together and compute force means and ranges. Where interesting differences were noted further amplification is presented. Foot-assembly evaluations are compared on an individual basis

dividual transducer locations, mounting ring positions, important dimensions and the sign conventions used. All forces are expressed in kp and moments in kp-mm. Unless otherwise stated forces are interpreted as acting on the brace. Reactions on the leg are equal and opposite in direction.

General concepts used in the analysis of results are illustrated in the consideration of axial loading during stance and swing phase. During stance phase axial forces registered at the ankle transducers indicate the combined effect of body weight, brace weight above the ankle, muscular activity within the brace and ground reaction. In order to separate body-weight forces from muscle-activity forces it is necessary to look at that part of the cycle where the other's contribution is minimal. The brace weight is assumed constant. From EMG studies reported (Eberhart et al., 1947) muscle activity is greatest during late stance-early swing and late swing-early stance corresponding to the periods of acceleration, deceleration and weight-acceptance stability (Fig 27)

During the middle part of stance phase the body is riding forward on the brace and weight-bearing loads are maximal.

Toe clearance is normally accomplished by hip and knee flexion and ankle dorsiflexion. In the test brace with a locked knee, toe clearance depended on circumduction, hiking of the pelvis and ankle dorsiflexion, when the ankle was free. During swing phase the ankle transducer forces reflect the

brace weight not suspended from the upper thigh, shoe assembly wt. 0.8 kg, upward accelerating forces from the foot if distal migration of the brace has occurred at toe off and forces caused by any attempted hip, knee or foot motion against the confines of the apparatus.

Muscle forces are expected to exert their greatest effect on the system during late stance-early swing and late swing-early stance, while maximal weight bearing forces occur during mid stance when the upward accelerations are taking place (FP1, FP2). This means that the best part of stance phase to evaluate a test brace's weight-relieving effectiveness, irrespective of muscle loading, is between foot flat and heel off.

The axial loading patterns recorded throughout the gait cycle are a result of these interactions. By similar analogy somewhat lesser forces appear along the X and Z axis.

#### Abbreviations used in the text

HS = heel strike

FF = foot flat

FP1 = 1<sup>st</sup> vertical floor maximum

FP2 = 2<sup>nd</sup> vertical floor maximum

HO = heel off

TO = toe off

MS = mid swing

#### Gait Pattern

The subject's, i.e. the author's, gait was evaluated by an orthopaedic surgeon, the orthotist in charge of the brace workshop and the author who could observe himself in a mirror at

Figure 28. *Lateral view.*  
Author in the brace during mid stance phase. Note foot-switch circuit wiring attached to the shoes

Figure 29. *Front view.*  
Just before heel strike. Note pelvic hiking on the normal side.

the end of the walkway. The typical gait pattern displayed slight vaulting during stance phase on the braced side. Toe clearance during swing phase was accomplished by ankle dorsiflexion and circumduction on the braced side and pelvic hiking on the opposite

side. Viewed from in front, the stance phase was abducted 0—5 deg., and from the side the long axis of the brace was inclined posteriorly from the vertical 14 deg. at heel strike decreasing to 7 deg. at toe off (Fig 28, 29, 30).

## MEAN LOADING TRENDS

### Axial loading (Y) Table 2, Fig. 31

Axial forces were exerted throughout the gait cycle, including swing phase, except with a patten bottom frame. This is explained by the fact that brace combinations with a shoe were loaded by forces transmitted from foot movements within the shoe.

In the patten bottom brace forces could not be transmitted to the brace because the foot was unattached to the patten frame.

### Anterior-posterior loading (X)

During the period heel-strike-to-first-force maximum the largest forces were recorded in the seat shell and were directed posteriorly. The thigh shell resultant is posteriorly directed and probably reflects the acceleration of the upper thigh against the posterior wall (Appoldt & Bennett, 1968). At the second force maximum the resultant became anterior and then posterior at heel off and mid swing. The AP thigh shell and calf band force distribution during swing phase correlates with the angular moment necessary to accelerate the leg in the line of progression.

Table 2 Range of forces (kp) during ambulation Body weight is 61 kp

	UP-DOWN		MEDIAL-LATERAL		POSTERIOR-ANTERIOR	
seat	-1.0	+39.0	-2.5	+10.5	-20.0	+4.2
corset	-10.5	+15.5	-6.7	+0.8	-6.7	+9.0
calf	force not measured		-6.0	+10.0	-7.0	+10.0
ankle	0.0	+7.0	forces not measured			
floor	0.0	+7.7	forces not measured			

## Medial-lateral loading (Z)

Seat and calf forces were lateral and opposite to the corset forces and produced a medial bending effect against the brace and shearing forces against the leg. Possible causes of this phenomenon are the normal valgus thrust of the knee (Perry 1967) and vertical loading of the brace in abduction.

## Loading From Muscle Forces

Loading was produced on the brace by attempted hip, knee and foot motion while standing non weight bearing (Fig. 32). Since the brace is rigid and attached to both ends of the limb, axial shortening or lengthening loads caused by attempted joint motion will produce opposite tensile and compressive loads on the brace and leg.

Non weight-bearing forces along the brace's axis were recorded before and during the applied forces from attempted joint motion. Longitudinal before-loading values ranged from 2—7 kp indicating the weight of the brace plus

the presence of unavoidable muscle activity. Plantar flexion produced a compressive instead of the expected tensile effect which can be explained by a slightly anterior alignment of the ankle joint with respect to the caliper frame (Table 3).

## Mean Moments

Moments are expressed in kp-mm units (Fig. 33) and interpreted as being applied to the brace.

## Torsional moments

Torsional moments about the longitudinal brace axis (Y) were internally directed from heel strike to the first force maximum. They became external at the second force maximum and then internal again during swing phase. This sequence correlates with the pattern of transverse inter-segmental moments generated by an unbraced limb, but is smaller in magnitude (Murdoch, 1970).

Table 3. Loading (kp) due to attempted joint motion while standing non weight bearing

Figure 3j

## Anterior-posterior moments

The large posterior moments exerted on the seat shell were caused by body weight forces applied to the ischial platform, which is posterior to the medial-lateral (Z) axis of rotation. In addition, a small downward component is provided from forward flexion of the pelvis during early swing phase (Strohm et al., 1963).

## Medial-lateral moments

During mid stance medial moments are exerted primarily on the seat shell, which correlates with the greater axial loading on the medial side of the brace. At heel strike and toe off seat moments became lateral possibly reflecting the preparatory movements of the body to meet these transitional phases.

## Interpretation of moments

Table 4 lists the moments about the X, Y, Z axes of the upper segment's measuring rings in four closed seat shell braces with different foot assemblies. Where no moments are listed under FP2 it means that no definite FP2 existed on the ankle force tracing. Patten bottom braces do not have a FF or HO phase.

Pooled trends have been shown in Fig. 33. It is evident that the moments are different in each segment and vary during the gait cycle. The greatest moments were exerted when the forces along the Y axis were largest. Moments were largest in patten bottom combinations and occurred primarily on the seat shell. With shoe assemblies the moments were less because part of the weight bearing forces responsible for the moments shunted through the limb directly to the ground. During mid stance phase more loading was transferred to the corset and the moments acting on this segment increased.

## LOADING DISTRIBUTION WITHIN THE BRACE

Weight relief refers to the amount of body weight transferred to the brace. By comparing the ankle transducer recordings with the body weight of 61 kp it is possible to assess the unweighting effectiveness of a particular test brace. Fig. 34 compares 8 different brace combinations, closed and open seat shell types, each with 4 different foot assemblies. Weight transfer was complete in the patten bottom braces

which is expected since there is no foot-ground contact. The other combinations displayed a progressively lower FP2 loading in the fixed, heel-hinge and free-ankle combinations respectively which suggests that the skeletal loading increased as the subject rolled forward into his metatarsal heads. All combinations except the patten bottom types displayed a progressive decrease in unweighting toward the latter part of stance phase.

Fig. 35 compares the three groups with different thigh-shell configurations in free and fixed ankle assemblies. Although the group with an open corset was tested with a nonabducted gait, the marked difference in loading recorded is primarily attributed to the small corset segment which is unable to accept any weight transfer

## Comparative load distribution in the medial and lateral uprights

Comparative loading of the medial and lateral uprights was studied at the ankle level for abducted and non-abducted gait patterns (Fig. 35). The lateral upright loading was smaller and of a different pattern than the medial upright. During the loading period foot-flat-to-force-maximum-two, abducted gait produced 3-7 times greater axial forces on the medial upright. This asymmetry was not present during the same period in non-abducted walking.

## Level of weight transfer

The closed seat and open seat shell

## Anterior-posterior moments

The large posterior moments exerted on the seat shell were caused by body weight forces applied to the ischial platform, which is posterior to the medial-lateral (Z) axis of rotation. In addition, a small downward component is provided from forward flexion of the pelvis during early swing phase (Strohm et al., 1963).

## Medial-lateral moments

During mid stance medial moments are exerted primarily on the seat shell, which correlates with the greater axial loading on the medial side of the brace. At heel strike and toe off seat moments became lateral possibly reflecting the preparatory movements of the body to meet these transitional phases.

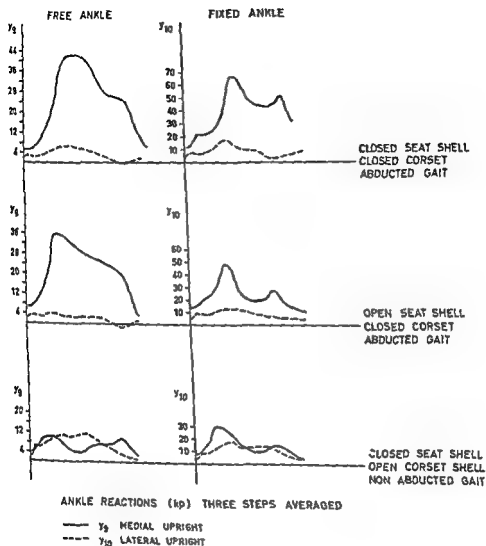

Figure 35

brace combinations were pooled, the average seat and corset forces computed and then expressed as a percentage of the total thigh shell load (Fig. 36).

In all cases the greatest percentage of the total thigh shell load was borne by the seat shell. However, in the open seat shell types without an anterior retaining wall, ischial contact was decreased resulting in more weight being transferred to the corset. This is shown by the corresponding increase in load percentage on the corset.

### Calf band forces

Calf band forces along the X and Z axis were recorded for selected runs and their patterns compared with different foot assemblies for different alignments. Although signs sometimes differ between the test-brace patterns, the overall force trends are similar for similar braces. Group III differed more than groups I and II and is most likely explained by the changes in leg alignment permitted by the diminutive corset segment during dynamic loading.

Figure 36

### Free ankle — Rotational Alignment

Free ankle force patterns are shown in Fig. 34, 35 and 37. Fig. 37 compares the effect of changing rotational alignment of the stirrup and illustrates the general force trends. At heel strike the leg is exerting anterior forces against the calf band. This pattern became progressively posterior and lateral peaking at the first vertical floor maximum. As the leg begins to pivot

forward it produces more anterior calf band forces again which peak just before toe off. Different rotational alignments showed essentially similar force trends.

### Free and fixed ankle combinations

Free and fixed ankle combinations were compared in the test brace having a closed seat shell and open corset shell. The essential differences be-

Figure 37

Figure 38

Figure 19

tween fixed and free ankles are the lack of plantar flexion at heel strike and dorsiflexion (toe clearance) at toe off. This problem is less for the fixed plantar flexed position at heel strike and the fixed dorsiflexed position at toe off. Hence one would expect to see similar force trends, compared to a free ankle, at the beginning and end of stance phase with plantar flexed and dorsiflexed positions respectively. These predictions are substantiated in Fig. 38.

### Comparison of four standard foot assemblies

Different foot assemblies consisting of a patten bottom, fixed ankle (neutral), caliper heel hinge and a free ankle (15 deg. of ext rotation) were compared with the two basic thigh-shell configurations (Fig. 39). The free and fixed ankle patterns have already been described. A heel caliper hinge is eccentrically located compared to the anatomic ankle joint. During plantarflexion the leg presses forward against the calf band, while dorsiflexion produces an opposite posterior force. This effect is demonstrated by a 10 kp sharp anterior force peak occurring with plantarflexion and just before the first force maximum. As the leg pivots forward and ankle dorsiflexion begins, these forces reverse but are not as large. The 10 kp reaction force exerted posteriorly against the anterior tibial border would produce an extension moment about the knee.

In the patten bottom brace type distal alignment of the leg was main-

tained by the calf band alone. The posterior force peak corresponds to the first force maximum. As the leg pivots forward the posterior force decreases and in the open seat became positive near toe off.

Figure 40

## FOOT-POSITION AND FLOOR MAXIMUM RELATIONSHIPS

Floor-contact periods for each foot position and the timing of FP1 and FP2 for all steps in each walk (except the first and last) were determined, averaged and expressed as a percentage of the total stance phase time. The results were compared against averaged walks without the brace and between the braced and unbraced sides for each walk (Fig. 40). Compared to

unbraced gait, with the left leg braced, the right side showed an earlier FP1, longer HO-TO, and FP2 closer or within HO-TO. The braced leg demonstrated a longer HS-FF, FP1 close to or within HS-FF, shorter HO-TO and earlier FP2 in FF-HO. The greatest changes occurred with fixed ankle combinations where HS-FF was prolonged with FP1 usually occurring well within this period indicating that the full impact of weight acceptance was borne on the heel.

## DISCUSSION

The data presented was obtained from the force-time histories recorded with an instrumented test brace capable of simulating selected ischial weight-bearing brace combinations. The appliance was 2—3 kg heavier than standard designs, less flexible and lacked contouring. These differences arose from the construction details which were necessary to achieve a lower instrumentation error and a greater versatility. The instrumentation and test methods proved to be a suitable tool for investigating the variables outlined. Because one normal subject was used his biomechanical interactions with the brace are not considered necessarily representative of other normal subjects or patients requiring orthoses. However, the force patterns and envelopes described have helped to take a closer look at the effectiveness of certain general bracing techniques and learn more about the load distribution within brace structures. The net effect on the leg is determined from an analysis of these findings.

### Floor contact patterns

Small changes in the duration of the foot positions and force-peak timing,

not readily observable, were detectable by the foot switch circuit.

A normal gait without the brace, but at the same test speed showed the first force peak to occur in early Foot-Flat-to-Heel-Off phase, permitting the upward acceleration of the trunk to be applied gradually and distributed more evenly over the foot. With fixed ankle assemblies, the Heel-Strike-To-Foot-Flat period was prolonged and contained the first force maximum which indicates that the full impact was borne on the heel.

### Loading distribution in the brace

Weight relief means the transference of body weight to the brace's structures. The location of this transference determines the level of skeletal unloading. Thigh shells with an anterior wall in the seat segment carried a more proximal distribution of the total load. This indicates that an anterior wall is important in order to maintain optimal ischial contact with the seat platform.

On the braces with different foot assemblies which were evaluated, the patten bottom types provided complete weight transference during stance

phase, however they are uncomfortable and present instability problems (Lehmann et al. 1970). The braces with shoe combinations demonstrated lesser degrees of weight-relieving effectiveness. Although the fixed ankle with metal sole plate is considered necessary to reduce metatarsal head loading during late stance phase, in this study it actually was associated with greater loading than with the free ankle. Variability between runs could account for this apparent paradox but another contributing factor may be the unseating effect produced by a greater jolt at heel strike.

Swing phase loading patterns were recorded on the brace and suggested a contribution from muscle activity. The same interpretation has been reported by other workers (Kirkpatrick et al. 1969 and Magora et al., 1968). Consequently, investigations were undertaken to evaluate this possibility. Loading against the confines of the apparatus showed that the largest forces were produced with knee flexion, hip flexion-extension and ankle dorsiflexion plantarflexion in that order. That muscle forces of some magnitude can occur in a partially immobilized limb is supported by Schenck's et al (1969) studies on instrumented short-leg plaster casts. He found that stresses were often higher during swing phase than stance phase.

It is concluded that the axial swing phase loading resulted from muscle activity plus any brace weight above the transducers not suspended by interface friction with the leg. Swing

phase axial loading was not seen in the patten bottom types where ankle motion was independent of the brace. Forces were exerted on the braces with a shoe assembly connected. Assuming equal suspension forces at the thigh shell interfaces, and the presence of patterned ankle dorsiflexion to provide toe clearance, this loading must have been caused by muscle forces transmitted from foot movements within the shoe.

### Unequal loading

The greater loading of the medial upright in a slightly abducted gait suggests that lighter designs might be possible using a single medial upright or lighter lateral upright.

The abducted gait and normal valgus thrust of the knee (Perry 1967) are considered to be the main causes of the bending loads recorded by the brace.

Comparison of calf band force patterns produced with a caliper and ankle hinge showed a marked difference. Calipers are normally inserted in the heel region which is poorly aligned with the anatomic ankle joint. During ambulation in a short leg brace this malalignment is usually not a problem because the eccentric rotations are converted to a compensatory sliding motion up and down the calf. In the long-leg test brace this compensatory motion was not possible. Instead, the lower leg was pressed anteriorly against the calf band with forces ranging up to 10 kp during plantar flexion. Since the reac-

tion against the leg is posterior, a concomitant extension moment at the knee is produced. The possibility of using this moment to dynamically stabilize a weak knee in early stance phase is suggested.

That moment differences occurred between the seat and shell segments is partly related to the dynamic interactions influencing the leg and whole brace, partly to the changing force distributions which occurred between the shell segments during the gait cycle and partly to the additional forces applied above the hip by the pelvis to the seat-shell extensions. The significance of these differences clinically with respect to the effects on the contained thigh segment is not entirely clear. Further, shell forces applied to the thigh's soft tissues are not necessarily transmitted wholly to the underlying femur. If rotational stability is desired, such as to protect a femoral fracture, then torque applied to or by the braced leg should be exerted proximally (in order to by-pass the fracture).

From a comparison of torque distributions in the seat and corset shell segments of different test brace combinations it is apparent that the largest and most proximally exerted torques

were produced when brace loading was greatest at the seat. Thus, in order to concentrate the applied torques proximal to a femoral shaft fracture, thereby enhancing rotational stability, a long-leg brace used for ambulatory fracture treatment should provide ischial weight-bearing capabilities.

Inadvertant swiveling of the braced leg on its heel with the attendant torque effect can be minimized by shortening the Heel-Strike-To-Foot-Flat period. Since fixed ankles prolong this susceptible period a free ankle should be used when torque effects must be avoided.

The effects of a disparity in anterior-posterior or medial-lateral moments is more difficult to evaluate. Because the leg and brace are assumed to be in equilibrium one moment must be counterbalanced by another. The large posterior moment demonstrated at the seat must be counterbalanced somewhere more distally on the thigh. For a recent fracture this could have either a stabilizing or disrupting influence depending on the fracture level. If dynamic stabilization of fractures is possible it will be accomplished by providing the proper moment and force interactions against the fragments.

## SUMMARY AND CONCLUSIONS

1. Research in the field of lower extremity orthotics is hampered by a lack of quantitative clinical data which is necessary to correlate clinical findings with a particular brace.
2. Clinical evaluation of a lower extremity orthotic device used during ambulation must be supplemented by a quantitative analysis to understand the biomechanical nature of the interacting systems.
3. The test brace and experimental method herein described has proved to be a useful research tool in acquiring force-time histories on testwalks representing ischial weight-bearing brace combinations worn by the author
4. Body weight transmission to the brace was complete only in the brace types with a patten bottom. Brace combinations with shoe attachments failed to completely unload the leg and became progressively more ineffective toward the latter part of stance phase. This resulted partly from incomplete transmission of bodyweight to the brace and partly from patterned muscle activity against the confines of the apparatus.
5. An anterior (closed) seat-shell wall is necessary to maintain effective ischial platform contact. Closed seat thigh shells demonstrated more proximal and more effective weight relief than the open seat thigh shell brace types tested.
6. Muscle forces voluntarily exerted against the confines of the brace with a shoe attachment were documented. Their role in producing swing phase loading was established. From patterned gait habits these muscle forces act to produce tensile limb loading during swing phase.
7. Braces with fixed ankle assemblies showed less weight relief than free ankle types. This may have been related to an unseating influence caused by the greater jolt effect felt during heel strike. Because of the prolonged heel strike period, full weight acceptance is borne on the heel instead of the whole foot as occurred with free ankle assemblies.

tion against the leg is posterior, a concomitant extension moment at the knee is produced. The possibility of using this moment to dynamically stabilize a weak knee in early stance phase is suggested.

That moment differences occurred between the seat and shell segments is partly related to the dynamic interactions influencing the leg and whole brace, partly to the changing force distributions which occurred between the shell segments during the gait cycle and partly to the additional forces applied above the hip by the pelvis to the seat-shell extensions. The significance of these differences clinically with respect to the effects on the contained thigh segment is not entirely clear. Further, shell forces applied to the thigh's soft tissues are not necessarily transmitted wholly to the underlying femur. If rotational stability is desired, such as to protect a femoral fracture, then torque applied to or by the braced leg should be exerted proximally (in order to by-pass the fracture).

From a comparison of torque distributions in the seat and corset shell segments of different test brace combinations it is apparent that the largest and most proximally exerted torques

were produced when brace loading was greatest at the seat. Thus, in order to concentrate the applied torques proximal to a femoral shaft fracture, thereby enhancing rotational stability, a long-leg brace used for ambulatory fracture treatment should provide ischial weight-bearing capabilities.

Inadvertant swiveling of the braced leg on its heel with the attendant torque effect can be minimized by shortening the Heel-Strike-To-Foot-Flat period. Since fixed ankles prolong this susceptible period a free ankle should be used when torque effects must be avoided.

The effects of a disparity in anterior-posterior or medial-lateral moments is more difficult to evaluate. Because the leg and brace are assumed to be in equilibrium one moment must be counterbalanced by another. The large posterior moment demonstrated at the seat must be counterbalanced somewhere more distally on the thigh. For a recent fracture this could have either a stabilizing or disrupting influence depending on the fracture level. If dynamic stabilization of fractures is possible it will be accomplished by providing the proper moment and force interactions against the fragments.

8. The caliper heel hinge because of its axis eccentricity with respect to the anatomic ankle joint caused a sharp posteriorly directed force build up to 10 kp against the leg at the calf band during plantar flexion, just before full weight acceptance. Since the effect on the knee would be an extension moment, it should be possible to use this force for dynamic stabilization of a weak knee during that critical period when other factors are causing flexion moments.
9. Axial loading of the medial upright was increased up to 7 times greater than the lateral upright when walking in slight abduction. The design implications are that when this gait pattern is present, the use of a lighter lateral upright or a stronger single medial upright may be possible.
10. The best rotational stability within the mid thigh-shell area was achieved when applied torsional moments were exerted proximally. From a comparison of the torsional moments in different combinations, this condition was optimized with a closed seat shell and patten bottom brace. Thus when optimal torsional stability is required a long-leg brace with ischial weight-bearing features is desirable.
11. Anterior-posterior and medial-lateral moments computed for the corset and seat shell rings were compared and considered. Their relevance to dynamic fracture stabilization is discussed.
12. Different rotational alignments of the ankle stirrup assemblies produced no distinguishing force patterns. The calf band loading trends recorded for different fixed ankle positions varied between anterior forces up to 2 kp for the plantar flexed position to posterior forces up to 2 kp for the dorsiflexed position. The fixed neutral ankle cycled between these ranges. Patten bottom, free and heel hinge assemblies produced higher forces ranging between 7 kp of posterior force for a patten bottom to 10 kp of anterior force with a caliper heel. These larger values are attributed to the less restricted walking patterns and the magnifying effect ankle motion produces on hinge malalignment.
13. A foot-position floor contact switch is described which synchronizes force maximum timing and foot positions with separate recorders by marking the analogs simultaneously.

## INTRODUCTION

✓ The term « Soudure autogène », introduced by Danis in 1949, has been used to characterize the roentgenological healing pattern in compression osteosynthesis with a plate or screws and implies that a fracture gap is gradually eliminated during the healing phase. This type of fracture healing, at which the AO group aims, goes under the name « primary bone healing » (Müller et al. 1961). Characteristic of this healing process is considered to be the absence of roentgenologically visible periosteal callus, which means that the compression osteosynthesis gives satisfactory stability. Provided that the medullary circulation is intact, the development of callus obviously shows an inverse relationship to the degree of stability (Yamagishi & Yoshimura 1955, Andersson 1965), and periosteal callus in compression osteosynthesis would thus seem to be a sign of disturbed healing (Wieser & Allgower 1962). The compression as such probably only means increased stability, while the healing rate is hardly accelerated. Geiser (1963) and Charnley (1965) claim that increased periosteal destruction during the operative procedure can be a cause of reduced callus development. In experiments on the sheep radius, Shenk & Willenegger (1963) showed that regenerating osteones pass over an osteotomy line. These authors consider that this form of healing, which with its secondary osteone formation resembles the rebuilding of normal cortical bone is worth striving for. They consider that under stable conditions the devitalized marginal layer of the cortex would induce regeneration of the Haversian systems (Shenk & Willenegger 1967). Geiser (1963) claims, however, on the basis of studies on rabbits, that all bone healing arises from periosteum and endosteum. This bone formation primarily fills out the fracture gap, while at the same time there is creeping substitution of the necrotic marginal layer. // On the basis of

microangiographic and fluorescence microscopic studies in compression osteosynthesis on the dog tibia, Olerud & Danckwardt-Lillieström (1968) consider that new bone is formed mainly from blood vessels arising from the medullary cavity and periosteum, but that at the same time, under certain conditions, intracanalicular bone formation is possible.

Thus, opinion on the importance of the different healing courses are somewhat divergent. By introducing an avascular intermediate fragment into the compression zone, we have found it possible to study more closely the way in which the revascularization of an « extended » marginal zone takes place and the source of the main vascular supply. With the microangiographic technique used especially by Göthman (1960), Rhinlander (1962, 1968) has studied the revascularization of diaphyseal fractures. He has pointed out that the healing area in non-dislocated fractures obtains its essential vascular supply from the medullary cavity.

The aim of the present study was to elucidate the healing course on the incorporation of a completely devascularized, diaphyseal intermediate fragment, comprising the whole circumference of the diaphysis in a compression osteosynthesis with a plate.

## METHOD

The study was performed on adult, mongrel dogs.

From an incision immediately lateral to the anterior tibial margin, the medial facet of the tibia was dissected free subperiosteally. A 6-hole AO plate was placed in position and fixed with screws through the 3 distal holes. The upper part of the plate was anchored with the compression instrument developed by AO. The fitting of the compression plate before the osteotomy was of great importance for the subsequent osteosynthesis. The plate was bent so that the osteotomy gaps of the fibular side should be compressed slightly before the gaps of the medial side. When the plate had been removed after the fitting, a double osteotomy was performed with a Gigli saw, corresponding to the area between the middle holes of the plate. The intermediate fragment was made somewhat broader against the plate side. The ring-shaped intermediate

fragment then obtained was lifted out of its bed and was thereby completely freed from vascular communications. The osteotomy surfaces were smoothed with a file until they were quite even, after which they were washed with physiological NaCl solution. The intermediate fragment was replaced in its position and the AO plate was secured in place. After fine adjustment of the fractures to an exact position, the compression was performed. On compression, the intermediate frag-

FIG 1 - Diagram of the experimental arrangements. On compression, the fibular side is first adapted, on further compression the plate is straightened and the plate side is brought under compression. The intermediate fragment is pressed down into its bed when the inner screws in the right and left main fragment finally are tightened.

ment, owing to its shape, was pressed firmly between the main fragments and the plate, so that the internal fixation was maximally stable. The part of the fibula between the levels of the osteotomy was resected, so that a continuity defect was produced at this site. The main incision was closed with single intracutaneous nylon sutures. The operation area was drained for 24 hours with a Kofferdam strip. The experimental set-up is presented schematically in Fig. 1.

All operations were performed on both tibiae, as a rule with an interval of 4-6 weeks. In order to label the newly formed bone, the dogs were given two injections of Terramycin® (Pfizer)

FIG. 2 - Roentgenograms showing the position of the intermediate fragment in the tibial diaphysis and the healing of the osteotomies: *a* - After an observation time of 4 weeks. The osteotomy gaps are still well visible but endosteal callus is present, especially in level with the lower gap *b* - After an observation time of 6 weeks. The lower osteotomy gap is almost completely filled, and the upper gap is partially open. The fibular part of the intermediate fragment is undergoing pronounced reconstruction *c* - After an observation time of 8 weeks. The lower osteotomy gap shows a tendency to delayed union, and the upper gap is almost filled. The structure and mineral content of the intermediate fragment are essentially retained *d* - After an observation time of 10 weeks. Both osteotomy gaps healed. Considerable reconstruction of the intermediate fragment and especially the marginal zone of the upper main fragment *b<sub>1</sub>* - enlargement of the 6 week preparation *d<sub>1</sub>* - enlargement of the 10 week preparation

These were given intraperitoneally (50 mg/kg body weight), one of them 1-2 weeks after the second operation and the other 2 days before the end of the experiment. The experiment was arranged so that specimens were obtained during the healing process at 4 weeks and up to 14 weeks, at intervals of 1-2 weeks.

At the end of the experiment the dogs were again anaesthetized. After primary heparinization (500 U Vitrum/kg), a catheter with an internal diameter of 1.5 mm was introduced into the carotid artery in the direction towards the heart. Through this catheter an Indian ink mixture (200 ml Günther Wagner Pelikan Indian ink in 800 ml isotonic NaCl) was infused with an ordinary Record syringe, at the beginning with excess pressure. After infusion of about 100-200 ml the animal usually died, after which the infusion was continued slowly for a further few hours until 5 litres of Indian ink mixture had been given from a height 120 cm above heart level. During the period of the infusion the dogs were kept in an upright position so that the Indian ink solution should gradually sediment in as many vessel branches as possible in the freely dependent limbs.

After the Indian ink filling procedure the extremities were amputated at the knee joint and fixed in 96% alcohol which was changed daily or on every alternate day for 14 days. The soft tissues were cut away except on the area nearest to the osteotomy. The osteosynthesis plate was removed, and the specimens were photographed roentgenologically. The specimens were divided into two halves; one half was embedded in methyl methacrylate and the other was decalcified for paraffin embedding.

The paraffin embedded specimens were sawn into 1 mm thick sections, the paraffin was dissolved in xylol, and the sections were then placed in sodium benzoate and wintergreen oil according to the Spalteholz technique.

The plastic-embedded halves were sawn into ½ mm thick sections, parallel with the longitudinal axis of the bone, and were then ground down to a thickness of about 80-100 µ. These sections were studied microscopically with ultraviolet light with a filter combination suiting Terramycin fluorescence.

Some of the ground, plastic-embedded sections were photo-

FIG 2 - Roentgenograms showing the position of the intermediate fragment in the tibial diaphysis and the healing of the osteotomies: *a* - After an observation time of 4 weeks: The osteotomy gaps are still well visible but endosteal callus is present, especially in level with the lower gap *b* - After an observation time of 6 weeks: The lower osteotomy gap is almost completely filled, and the upper gap is partially open. the lower leg developed in these dogs. The remaining 6 dogs showed only moderate swelling 4 weeks after the operation and later. There were no infections. The roentgenograms showed a distinct osteotomy gap in the 4-week specimens (Fig. 2). These gaps were almost completely filled after an experimental period of 8 weeks, in accordance with Danis « Soudure autogène ». At 10-11 weeks the fracture gap could no longer be visualized roentgenologically (Fig. 3). In the 2 pseudarthrosis cases the upper gap had healed after 8 and 10 weeks, respectively.

On several roentgenograms a cloudy callus reaction a few mm high was observed on the medial side of the tibia. The intermediate fragment showed on some roentgenograms a considerable reduction of the calcium content in comparison with the main fragment (Fig. 2)

Fig 4 - Spalteholz specimen 4 weeks after osteotomy. Microangiography shows that vascular communication has been established between the main fragments through the medullary cavity of the intermediate fragment. A vein is here connecting the vascular systems of the two main fragments through the previous avascular intermediate fragment. More than the inner 2/3 of the cortex of the intermediate fragment is vascularized from the medullary cavity. The intermediate fragment is surrounded by a thin periosteal vascular network, which is revascularizing the outer part of the cortex.

graphed microroentgenologically for a study of the roentgenological microstructure, and examined in polarised light with respect to the course and orientation of the collagen fibrils.

## RESULTS

In spite of the mechanically rather unfavourable experimental arrangements, with double osteotomy, only about one week elapsed before the dogs bore weight on the affected limb when walking. There was some limp, however, for a period of up to 3 weeks in the dogs which healed without complications. In 2 of the 8 experiments pseudarthrosis occurred in the distal osteotomy, and pronounced swelling of

FIG. 3 - Roentgenograms showing the incorporation of the intermediate fragment after 7 (*a*) and 11 (*b*) weeks, respectively. *a*<sub>1</sub> - Partial enlargement after observation time of 7 weeks. The osteotomy gaps are almost completely filled; moderate endosteal callus. *b*<sub>1</sub> - Partial enlargement of roentgenogram at observation time of 11 weeks. The two osteotomy gaps are no longer visible. Decreased mineral content in the intermediate fragment as a sign of reconstruction in progress. A tendency to spongy transformation within the distal main fragment.

both the plate side of the tibia and its lateral side. At the same time, in only exceptional cases were periosteal vessels (perhaps better expressed as vessels arising from the soft tissues, since the periosteum was largely destroyed) found to pass deeper into the cortex than some mm, i.e.  $1/4 - 1/5$  of the thickness of the cortex. This applied both to the plate side of tibia and its fibular side. Between the plate and the cortex a relatively richly vascular, fibrous soft tissue layer always extended (Fig. 7).

Fig. 6 Spalteholz specimen 6 weeks after osteotomy. Absolute bone contact between the fracture fragments at the fibular side. More than  $4/5$  of the cortex of the intermediate fragment is vascularized from the marrow canal. The osteotomy line is on the way to being crossed over by cutting heads from vessels in the intermediate fragment to the right (Partial enlargement of Fig. 5)

## ANGIOGRAPHIES

In specimens from experiments of the shortest period (4 weeks) the medullary circulation had become reestablished, with vascular communications crossing the two osteotomy lines (Fig. 4). With all probability, the well filled vessel constitutes an artery, and the broader vessel with less Indian ink density is probably a vein. Specimens from the 4th week also show that a large proportion of the primarily avascular fragment contained Indian ink filled vessels, the source of which was almost solely the medullary cavity. Fig. 5 demonstrates besides a well vascularized medullary cavity also a vascular system which extends from the medullary cavity almost to the outer layer of the cortex. This is found in Fig. 6, which is an enlargement of Fig. 5. The type of vascularization is the same. This held for

FIG 5 Spalteholz specimen 6 weeks after osteotomy The medullary cavity circulation is restored in the form of a relatively fine-meshed vascular network of the type seen in proliferative callus formation. Four-fifths of the fibular side cortex of the intermediate fragment is revascularized here from the medullary cavity Negligible periosteal revascularization, which is taking place during the formation of resorption cavities. Cartilage immediate outside the cortex between fibular fragment end (bottom to the right) and the intermediate fragment is undergoing enchondral ossification

both the plate side of the tibia and its lateral side. At the same time, in only exceptional cases were periosteal vessels (perhaps better expressed as vessels arising from the soft tissues, since the periosteum was largely destroyed) found to pass deeper into the cortex than some mm, i.e.  $1/4 - 1/5$  of the thickness of the cortex. This applied both to the plate side of tibia and its fibular side. Between the plate and the cortex a relatively richly vascular, fibrous soft tissue layer always extended (Fig. 7).

FIG. 6 - Spalteholz specimen 6 weeks after osteotomy. Absolute bone contact between the fracture fragments at the fibular side. More than  $4/5$  of the cortex of the intermediate fragment is vascularized from the marrow canal. The osteotomy line is on the way to being crossed over by cutting heads from vessels in the intermediate fragment to the right (Partial enlargement of Fig. 5)

An abundance of newly formed vessels were observed 4 weeks after the osteotomy in the fracture gap, where any form of space was present. The vessels originated mainly in the medullary cavity. It was often observed that medullary cavity vessels first entered the intermediate fragment or the main fragments and then passed further via Haversian canals to the fracture gap, there to connect with vessels with direct communication from the medullary cavity or from the periosteum (Fig. 8). When there was very close or absolute contact

FIG 7 - Spalteholz specimen 6 weeks after osteotomy. In the upper part of the specimen there is an empty space, which represents the position of the metal plate. Numerous vessels in a fibrous layer are invading the area between the cortex and the plate. The periosteal vessels seem to be contributing very little to the vascular supply of the cortex.

between the fracture fragments, there was no space for vascular invasion. The vascular supply then developed mainly into canals leading from the medullary cavity, lying in the fragments close to the fracture line. Blood vessels passed into these canals, and made contact with vessels from the other side of the fracture gap (Fig. 8). This took place partly via so called cutting heads (Fig. 9), which drilled their canals possibly quite independently of previous canals in the bone.

In specimens 6-8 weeks after osteotomy, a considerable widening of the Haversian canal systems was found both in

FIG 8 - Spalteholz specimen 5 weeks after osteotomy. Osteotomy line on the plate side of the tibia (top of the picture) Vascular invasion from both the periosteal and the endosteal side The entire osteotomy line is vascularized Several vascular communications with the Haversian systems of both the intermediate and the main fragment

FIG. 9 - Spalteholz specimen 4 weeks after osteotomy. The fracture line, which otherwise is not vascularized, has been traversed by the vessels in a secondary osteone. The foregoing cutting head in the intermediate fragment can be seen to the left of the gap.

FIG. 10 - Spalteholz specimen 4 weeks after osteotomy. Cutting head with well-filled vessel loop is just about to traverse the fracture line

the main and in the intermediate fragment. Not seldom, several vessels were then observed in the same canal. As described above, these canals can be completely newly formed by so called cutter heads. In cases with several vessels in the same canal, one vessel was often found to be narrower than another, i.e. the former was probably an artery and the latter probably a vein.

The cutting head mechanism was also observed regularly into the fracture gap, from both the periosteal and endosteal side. On either side of the fracture line of a closely

FIG. 11 - Spalteholz specimen 10 weeks after osteotomy. The intermediate fragment, which is seen to the left of the photograph, is penetrated by relatively wide vessels. The bone canals often contain more than one vessel. The vascular pattern in the medullary cavity indicates resorption of endosteal callus.

adapted fracture, a vessel loop was seen, which worked its way forwards into the marginal zone. The mechanism was most clearly evident on fluorescence specimens, however (Fig. 19).

The fracture gap and its immediately surrounding area became more and more vascularized with time. After an observation time of 10-11 weeks the fracture gap itself was only just distinguishable - so evenly was the vascular pattern distributed within the intermediate and main fragments. Some specimens

FIG 12 Spalteholz specimen 11 weeks after osteotomy. The osteotomy gap can be identified in relation to the divided fibula (in the lower part of the photograph). The cortical vessels in the osteotomy area are evenly distributed and show signs of maturity. They are mainly orientated in the longitudinal direction of the cortex. The intermediate fragment is to the right side of the photograph.

(Fig. 11) showed considerable absorption of cortical bone. Fig 12 gives a general picture of the angiographic pattern of an in-built intermediate fragment 11 weeks after the osteosynthesis. At this stage, direct vessels from the medullary cavity and periosteum to the fracture gap were seldom seen, so that these communications had probably re-formed even after this short time.

#### FLUORESCENCE MICROSCOPY - PERIOSTEAL REACTION

Four weeks after osteotomy, periosteal activity with newly formed bone was noted both over the main and the intermediate fragments. The bone formation was characterized by active tissue formation on the surface and resorption cavities in the deep areas immediately outside the original cortical bone (Fig. 13). At the level of the opening of the fracture gap new bone had developed in the form of almost fan-shaped trabecular bone (Fig. 14). On the fibular side, partly calcified cartilage had formed between the ends of the fibula and the intermediate fragment (Fig. 15).

FIG. 13 Fluorescence specimen 4 weeks after osteotomy. Periosteal callus is seen with active tissue formation on the surface, and resorption cavities containing wide vessels in towards the cortex.

adapted fracture, a vessel loop was seen, which worked its way forwards into the marginal zone. The mechanism was most clearly evident on fluorescence specimens, however (Fig. 19).

## ENDOSTEAL REACTION

Four weeks after osteotomy, active endosteal callus formation was seen, especially at the level of the fracture gaps. At a relatively short distance from the fractures gaps resorption areas were observed.

Five weeks after osteotomy there was still considerable activity at the level of the fracture gap, but it was more limited and concentrated. The resorption powers seemed to be clearly predominant (Fig. 18)

At an observation time of 6 weeks, the specimens showed practically only resorption in the medullary cavity, and 8 weeks after osteotomy the previously formed endosteal callus was almost completely resorbed. At later observation times endosteal bone formation activity was noted only exceptionally.

FIG 18 Fluorescence specimen 5 weeks after osteotomy Considerable activity within the endosteal callus at the level of the fracture line (visible in the lower middle part of the picture), although in other places resorption forces predominate

under construction. The second terramycin labelling 2 weeks after the first supported this observation (Fig. 16). The periosteal activity outside the fracture gap had decreased greatly in intensity, as indicated by the presence of resorption areas.

After an observation time of 8 weeks reconstruction of the periosteal callus and the subperiosteal bone had become more extensive, with a change-over to a new cortical structure (Fig. 17). Superficial activity within the periosteum was practically no longer observed, and this was also true at the level of the fracture gaps. Neither were any signs of active periosteal bone formation seen in specimens examined 10 weeks after the osteotomy. On the other hand, numerous resorption cavities were found within the area between the ends of the fibulae and the intermediate fragment, where endochondral bone formation was still observed.

Fig. 17 - Fluorescence specimen 8 weeks after osteotomy. Reconstruction and condensation of the periosteal callus. The borderline between the cortex and periosteal callus has disappeared. The superficial activity is of a different character than that observed at shorter periods after the osteotomy. The primary callus in the osteotomy gap is partially resorbed and penetrated by secondary osteones orientated in the longitudinal direction of the bone.

On the other hand, numerous resorption cavities were found within the area between the ends of the fibulae and the intermediate fragment, where endochondral bone formation was still observed.

FIG. 17 - Fluorescence specimen 8 weeks after osteotomy. Reconstruction and condensation of the periosteal callus. The borderline between the cortex and periosteal callus has disappeared. The superficial activity is of a different character than that observed at shorter periods after the osteotomy. The primary callus in the osteotomy gap is partially resorbed and penetrated by secondary osteones orientated in the longitudinal direction of the bone.

arches, one on either side of each osteotomy, had invaded the end of the fragments and eroded them (Fig. 19). Behind these eroding vessels (osteoclastic activity), bone was formed in the usual way (osteoblastic activity). The previously active resorptive forces were indicated by the formation of Howship's lacunae, which often filled rapidly with new bone, which formed a sharp borderline against the necrotic, avascular bone in the marginal zone.

Reconstruction zones with tetracycline labelling were found both in intermediate and main fragments. In dogs observed at

FIG. 20 : Fluorescence specimen 6 weeks after osteotomy. Cutting head in the main fragment on the way towards the osteotomy gap during formation of a secondary osteone. The thin arteriole divides into wide venous sinusoids.

4 weeks, on the right tibia only one labelling was observed in the intermediate fragment, and double-labelling in the main fragment was only seen at a distance of 1 cm and further from the osteotomy gap. At the time of the first labelling in this dog, i.e. 1 week after osteotomy on the right leg, no new bone formation was observed in the intermediate fragment or

in the area nearest to the fracture gap, but at that time there were probably already some functioning vessels.

In the specimens observed 4 weeks after osteotomy, Indian ink filled vessels were relatively numerous in the main fragment but considerably fewer in the intermediate fragment, which as yet showed only few resorption centres and isolated so called cutting heads (Fig. 20).

Five weeks after osteotomy, interfragmentary bone formation was seen to have taken place via vessels arising mainly from the medullary cavity but also from the periosteal side.

FIG. 21 - Fluorescence specimen 6 weeks after osteotomy. Centre of intermediate fragment Double-labelled secondary osteons show that bone formation has occurred in the intermediate fragment as early as 2 weeks after the double osteotomy.

These vessels often formed communications with vessels in Haversian canals on either side of the osteotomy gap. Double labelling was observed within one single osteone inside the intermediate fragment and very close to the fracture gap in the main fragment indicating, in accordance with the labelling of the specimens, that bone formation had occurred at these

sites after only 2 weeks following the osteotomy. Compared with the 4-week specimen, more numerous and larger resorption cavities were found (Fig. 21).

Six weeks after osteotomy, resorption cavities were seen within the bone primarily formed in the fracture gap (Fig. 22). The cavities also showed bone formation in the wall. A large number of vessels and osteones traversed the fracture gap (Fig. 23) In some areas where the fracture gap was not completely vascularized, the bone formation and bone resorption activities seemed to be completely ceased (Fig. 24), even

in the area nearest to the fracture gap, but at that time there were probably already some functioning vessels.

In the specimens observed 4 weeks after osteotomy, Indian ink filled vessels were relatively numerous in the main fragment but considerably fewer in the intermediate fragment, which as yet showed only few resorption centres and isolated so called cutting heads (Fig. 20).

Five weeks after osteotomy, interfragmentary bone formation was seen to have taken place via vessels arising mainly from the medullary cavity but also from the periosteal side.

#### MICRORADIOLOGICAL STUDIES

These studies showed the occurrence of low mineralized newly formed bone in the fracture gap in specimens observed at 4 weeks after the osteotomy, but only, however, in gaps wide enough to be invaded by blood vessels (Fig. 27). After a longer period, i.e. 6-8 weeks, on the other hand, profuse interfragmentary bone formation was seen (Fig. 28). This was easily distinguishable from the original bone by its lower mineral content and by the fact that the osteocyte lacunae were somewhat larger and rounder than in older bone.

Eight weeks after osteotomy, there was resorption of bone previously formed in the fracture gap, which favoured reorientation of the bone in the longitudinal direction of the cortex. Several specimens showed, in this situation, a relatively small

amount of new bone formation in the large resorption cavities (Fig. 29).

Microroentgenography of specimens 10 weeks after osteotomy showed that a considerable area of old bone on either side of the osteotomy gap and within the intermediate fragment

seemed to have been replaced by new bone. The originally formed bone in the gap with its orientation in the direction along the fracture line was traversed by new osteones with a structure oriented longitudinal to the cortex (Fig. 30). Even on

FIG 28 - Microroentgenogram 6 weeks after osteotomy. large extent in the longitudinal direction of the osteotomy gap, with a few connections into the cortex on either side of the gap (Fig. 33). This held mainly for gaps in which direct angiogenic, i.e. primary bone formation had occurred. In specimens observed 8 weeks after the osteotomy, newly formed secondary osteones were seen, which traversed the fracture gap and which had produced resorption cavities in the primary bone formed in the gap (Fig. 34). Collagen fibrils were found here to be partly oriented in the longitudinal direction of the cortex. The primary orientation of large parts of the collagen was seen to persist for a relatively long period, i.e. 10 weeks

FIG 33 - Polarisation photograph 5 weeks after osteotomy. The collagenous structures are mainly oriented along the osteotomy gap but have attachments here and there in the surrounding cortex. Intermediate fragment to the right and main fragment to the left.

and possibly even longer (Fig. 35) Several specimens exhibited numerous resorption cavities, especially within the intermediate fragment, an expression of active reconstruction and a spongy transformation of the cortical bone due to decreased elasticity and a reduced demand for strength on the bone fixed by the

shaped Howship's attachment into a fragment, means a defective anchorage which would only be reliable if there was contact with the deeper located osteones (Fig. 31). In specimens observed 11 weeks after osteotomy, the original bone was only seen in patches around the osteotomy gap which in this case was not

FIG 32 - Microroentgenogram from specimen 11 weeks after osteotomy. Intermediate fragment to the left. The old osteotomy line is just distinguishable immediately to the left of the midline. Reorientation of the bone newly formed in the fracture gap seems to be largely completed. The resorption is pronounced both in the intermediate fragment to the right and in the main fragment to the left. Bone from the time prior to the osteotomy is seen only in occasional patches. The bone is spongy in structure Compare fluorescence specimen in Fig 26

delimitable (Fig. 32). Both the fracture ends of the main fragments and the intermediate fragment itself thus exhibited considerable reconstruction, although this was still not completed within the total observation period of the experiment.

#### STUDIES IN POLARISED LIGHT

Examination of the specimens in polarised light showed that 6 weeks after the osteotomy the collagen fibres ran to a

compression plate. 10-12 weeks after the osteotomy a confusion of collagen fibres was seen within the ends of the fragments and within the bone formed in the fracture gap, but with a tendency, however, to orientation in the longitudinal direction of the cortex (Fig. 36). The fragment end was still apparent with some sharpness, however, indicating that the reconstruction was far from complete, in spite of the fact on macroroentgenograms the osteotomy gap showed complete bridging.

FIG 36 - Polarisation photograph from specimen 11 weeks after osteotomy. Main fragment to the right, where the osteotomy gap is identified by bone which has not yet been rebuilt, easily seen at the level of the middle of the photograph. The osteotomy gap itself is filled by relatively irregularly layered collagen fibres. In the upper half of the photograph, to the left, there is a longitudinal orientation of rebuilt bone in the intermediate fragment.

FIG 35 - Polarisation photograph from specimen 9 weeks after osteotomy. The orientation of the collagenous structure in the fracture gap has been maintained, but reorientation is in progress.

FIG. 34 - Polarisation photograph from specimen 8 weeks after osteotomy. The osteotomy gap is only slightly distinguishable. In the centre of the photograph, however, there is a well-developed collagenous formation passing from the right side of the main fragment to the left side of the intermediate fragment, straight through previously formed collagenous structures in the fracture gap.

FIG 35

teal growth still occurred during the 4th-6th week after a double osteotomy, an observation which was not made in the previously studied single osteotomy (Olerud & Danckwardt-Lillieström 1968). The periosteal growth took place rather slowly, however, and extensive resorption cavities developed in the bottom layer of the periosteal callus. Cartilage formation, as an expression of instability, occurred within the endosteum and on the compression plate side of the tibia only in cases of pseudarthrosis. On the other hand, cartilage formation was observed in all cases in the area between the fibular ends and the intermediate fragment. Thus there would seem to be more pronounced instability on the fibular side than on the plate side of the tibia. Two factors contribute to this. As mentioned previously, a screw-attached compression plate hardly fixed any other region than that close to the plate. On weight-bearing with such an osteosynthesis, movements always occur, which become increasingly greater the further the distance from the fixation centre of the plate. Another reason for the cartilage formation on the lateral side of the tibia may be the movements produced by the osteotomized but not fixed fibular ends.

The operative trauma in transverse osteotomy results not only in damage to the periosteal circulation but also to a cortical circulatory disturbance nearest to the osteotomy gap. The normal intracortical vascular supply arises mainly from the medullary cavity, and to the extent that screws cause damage to the medullary blood flow, a disturbance of the intracortical circulation occurs, with subsequent enlargement of the so called avascular marginal zone. This is certainly a factor of importance in bones with a small marrow canal. In several types of fracture, however, intracortical vascular damage is probably considerably greater because of extensive periosteal and endosteal destruction of blood vessels, caused by local thrombosis and possibly also fat embolisation.

The revascularization pattern in the enlarged, cortical avascular area which an avascular intermediate fragment comprises, does not differ from the revascularization system in single osteotomy. The medullary circulation would seem to play the largest role, since almost 4/5 of the cortex is revascularized from the endosteum. This also holds for the lateral side of the tibia, the periosteal circulation of which is not disturbed by

## DISCUSSION

The degree of stability is an essential factor for fracture healing. In the present investigation the prerequisites for satisfactory stability were fewer than in compression osteosynthesis of a simple, transverse osteotomy gap. This was indicated by the occurrence of pseudarthroses. A compression plate osteosynthesis will hardly give complete stability, since it is probably impossible to produce, by compression over the plate, exactly the same pressure conditions within the fracture gap on the compression plate side of a diaphysis as on the other side, which must obviously be a prerequisite for absolute stability. In the investigations by Shenk & Willenegger (1963) on the sheep radius, the stability was certainly favoured by the undisturbed ulna.

During the healing course, a roentgenologically just visible periosteal callus reaction was seen outside the double osteotomy lines. In our earlier study on compression osteosynthesis in simple osteotomy (Olerud & Danckwardt-Lillieström 1968), where the stability was probably considerably better, there was no roentgenologically visible periosteal callus reaction. The operative procedure in the two series were essentially similar and thus cannot explain the difference in callus reaction. For a certain period of time, however, it must be assumed that there will be a total elimination of the medullary circulation in the intermediate fragment, a circumstance which can have a contributory effect on the development of callus. The smaller degree of stability in the double osteotomy might also contribute to the increased periosteal surface activity.

Even after reaming the medullary cavity on osteotomized rabbit tibias, stabilized by nails, only small amount of periosteal bone was produced when the cortical damage was limited (Danckwardt-Lillieström, Lorenzi & Olerud 1970). In case of large cortical damage, because of intracortical fat embolization produced during reaming (Danckwardt-Lillieström 1969), the periosteal bone formation was extensive (Danckwardt-Lillieström et al. 1970).

The microscopic study of the fluorescence specimens showed an essentially increased periosteal activity in comparison with corresponding specimens with single osteotomy. Thus, perios-

ment side or from the intermediate fragment side. They then form direct secondary osteones. The primary bone formation according to Shenk & Willenegger then seems to take place but requires ideal conditions.

A third variation of vascular invasion into avascular bone occurs within the osteotomy gap itself. Vessels bore their way into the avascular edges of the fragment ends on either side of the actual fragment contact and form Howship's lacunae. The angiographic pattern is very characteristic and uniform and is most closely reminiscent of a pair of tongs which grasp the fracture gap from both sides. In principle, this activity is perhaps not greatly different from that represented by cutting heads. Close on the heels of these vessel loops follows newly formed bone, which fills out the gap between the fracture ends. By means of vascular contact across the Haversian canal systems, intracortical attachment occurs. Resorption alone, or predominantly, within the fracture area is seen from time to time but is not a general finding. Neither does resorption of marginal zones, as suggested by Bohler, occur in the avascular fragment. The reconstruction of the avascular fragment ends and the avascular intermediate fragment takes place gradually via established vascular canals, so to speak from the inside, and via cutting heads. The avascular structures thereby retain their stability and function. In this way new bone gradually takes over the functional stresses.

In those cases where space exist for endosteal and periosteal vascular invasion of the fracture gap, the gap often seems to be filled with bone after only 4-6 weeks. This primary new bone has relatively poor attachment in the avascular bone ends until vascular communications are made with the Haversian systems in the main fragment. In any case the newly formed bone is primarily orientated along the direction of the fracture line. Six to eight weeks after osteotomy, considerable resorption takes place within the bone newly formed in the fracture gap, to advantage of the formation of new secondary osteones, which cross over the fracture gap. This osteone formation corresponds the direct osteone formation (intra-canalicular bone formation) and also that osteone formation which takes place when newly formed vessels have to take a roundabout way over the cortical

the osteosynthesis material. The finding that the medullary circulation involves the greater part of the medial facet of the tibia is more easily explained, since the osteosynthesis material lies here in the way of periosteal revascularization. Peculiarly enough, however, the relatively abundant circulation in the fibrous layer surrounding the plate seemed not to have communication with the cortical circulation, either.

Bone canals from the medullary cavity widen both for widening old vessels and newly formed vessels, which bud further in towards the Haversian canal systems. Within the main fragments, contact is made with previously undamaged vascular systems on the one side, and new formed vessels on the other side. The outgrowth of vessels takes place up to the fracture gap, and to the extent that direct bone contact occurs here, communication is made with vessels arising from the fragment of the opposite side. If space allows, the osteotomy gap is also filled with newly formed vessels, mainly from the medullary cavity, which often make contact with the vessels growing from the Haversian canals. The primary vascular invasion is accompanied by bone resorption and bone formation both within the marginal zone of the main fragment and in the intermediate fragment.

The revascularization with the aid of the so called cutting heads is a process which, to judge by the number of cutting heads in the sections, seems to occur somewhat later than the primary revascularization. According to Shenk & Willenegger, such a cutting head erodes 50-80  $\mu$  per day, which means that 1 mm bone would be revascularized in 12-20 days. This revascularization process is thus very slow, and it must be asked whether it alone can be responsible for the total revascularization and bone reconstruction.

With a marginal zone of only 2-3 mm, and often it is considerably larger, blood vessels would hardly reach the fracture gap within the course of 6 weeks. By means of double labelling with Terramycin, we estimated the cortical avascularity in the end of the main fragment in this type of experiment to be about 8 mm.

The cutting heads followed by their vessel loops seem to be able, however, to traverse the fracture gap from the main frag-

## CONCLUSIONS

Instability seems to be an important factor in the development of periosteal callus. With adequate stability, the callus undergoes regressive changes long before the fracture is healed. With relative stability there is extended, though not especially active, periosteal callus proliferation, while at the same time regressive changes can be observed.

The development of blood vessels within avascular areas in the fracture region is favoured by rigid fixation and followed by early filling of interfragmentary spaces with primary osteones or trabecular bone though with relatively poor attachment to the avascular, cortical bone. Under certain conditions, viz. absolute bone contact across the fracture gap, intracanalicular bone formation can occur with direct formation of secondary osteones crossing over the fracture line. This process is time-consuming and thus cannot be solely responsible for the bone healing. A practically identical process with formation of cutting heads is developed on either side of the fracture gap if this does not permit primary vascular invasion. Reestablished circulation in already existing Haversian canals may join the rebuilding by direct local resorption and bone formation. The microangiographic technique used shows extensive and relatively rapid revascularization of the medullary cavity and of preformed cortical canals, where vascular invasion from the periosteal side into avascular cortex seems to play a secondary role. Intracanalicular bone formation over the fracture gap is dependent, as regards time, upon the size of the avascular marginal zone, and therefore bone formation from the endosteal and periosteal direction can often predominate. Primary osteones, i.e. the new formed bone laid down in the longitudinal direction of the fracture gap and the trabecular bone laid down within the fracture defect, are rebuilt simultaneously with the formation of secondary osteones across any fracture gap. The reconstruction of the avascular intermediate fragment takes place, under the conditions of this experiment, approximately concomitantly with the reconstruction of the fracture gap. Roentgenologically the fracture gap seems to be bridged after an experimental period of 10 - 12 weeks, but examination of the bone structure by microroent-

fragment end in order to cross the fracture gap. Thus in cases of large avascular marginal zones the primary bone healing, according to Schenk & Willenegger, means a timeconsuming healing process.

The above mentioned resorption cavities appearing in the bone primarily laid down in the fracture gap, can in detail be seen on microroentgenograms, where the course can be followed clearly. It is striking, however, that the resorption often seems to predominate over the process of osteone formation; in those cases where this rebuilding can be determined, the newly formed bone in the longitudinal resorption canals seem to be fairly sparse. This is possibly an expression of much too little strain in a diaphyseal area which is under the influence of a relatively inelastic metal plate. It would seem that a spongy transformation — the occurrence of a number of resorption cavities — of the cortex can develop if the bone is not subjected to the mechanical forces for which it is intended.

The number of newly formed secondary osteones which traverse the osteotomy gap will be decisive for the strength of the bone. The primarily formed bone in the fracture gap will have, in comparison with the secondary osteones, considerably weaker anchorage in the fracture ends, which will result in inadequate strength of the bone for a considerable length of time, despite the fact that roentgenologically the fracture is filled with bone. In this respect the polarisation studies complement particularly the microroentgenological studies. In polarised light, this experimental material relatively seldom showed collagen fibres with direct attachment on both sides of the osteotomy gap. This seemed to hold also for specimen from 10 - 12 weeks after the osteotomy, where despite a general longitudinal orientation the collagenous structures were still located relatively irregularly and as yet far from filling the entire cross section of the osteotomy.

The microroentgenological and polarisation studies thus indicated that a long period of reconstruction remained before the bone structure became normal. It may be asked whether normalization would, in fact, occur as long as the metal plate remained

## CONCLUSIONS

Instability seems to be an important factor in the development of periosteal callus. With adequate stability, the callus undergoes regressive changes long before the fracture is healed. With relative stability there is extended, though not especially active, periosteal callus proliferation, while at the same time regressive changes can be observed.

The development of blood vessels within avascular areas in the fracture region is favoured by rigid fixation and followed by early filling of interfragmentary spaces with primary osteones or trabecular bone though with relatively poor attachment to the avascular, cortical bone. Under certain conditions, viz. absolute bone contact across the fracture gap, intracanalicular bone formation can occur with direct formation of secondary osteones crossing over the fracture line. This process is time-consuming and thus cannot be solely responsible for the bone healing. A practically identical process with formation of cutting heads is developed on either side of the fracture gap if this does not permit primary vascular invasion. Reestablished circulation in already existing Haversian canals may join the rebuilding by direct local resorption and bone formation. The microangiographic technique used shows extensive and relatively rapid revascularization of the medullary cavity and of preformed cortical canals, where vascular invasion from the periosteal side into avascular cortex seems to play a secondary role. Intracanalicular bone formation over the fracture gap is dependent, as regards time, upon the size of the avascular marginal zone, and therefore bone formation from the endosteal and periosteal direction can often predominate. Primary osteones, i.e. the new formed bone laid down in the longitudinal direction of the fracture gap and the trabecular bone laid down within the fracture defect, are rebuilt simultaneously with the formation of secondary osteones across any fracture gap. The reconstruction of the avascular intermediate fragment takes place, under the conditions of this experiment, approximately concomitantly with the reconstruction of the fracture gap. Roentgenologically the fracture gap seems to be bridged after an experimental period of 10 - 12 weeks, but examination of the bone structure by microrent-

genography and in polarised light indicates that further rebuilding is required before a normal structure can be expected, if, in fact, normalization can be expected at all as long as the bone is fixed by a plate and screws.

## SUMMARY

The healing course of a fracture with a compression-fixed, avascular diaphyseal intermediate fragment comprising the whole circumference of the bone was studied by Indian ink microangiography, the Spalteholtz technique and labelling with Terramycin, among other methods. The two-levelled osteotomy was performed on dog tibias with a Gilgi saw. The osteosyntheses were produced by mean of compression over a metal plate according to AO.

1. Four-fifths of the revascularization of the intermediate fragment took place from regenerated medullary circulation. The marginal zones of the main fragments and the fracture gaps were revascularized in the same way.

2. Under the experimental conditions used, the intermediate fragment seemed within 2 weeks to be supplied primarily with some vessels through existing Haversian canal systems. In a secondary phase revascularization of the cortex took place via so called cutting heads.

3. As far as space allowed, the osteotomy gaps were invaded rapidly by newly formed vessels, which were followed, under stable conditions, by angiogenic bone formation.

4. Periosteal callus was developed both over the intermediate fragment and the main fragments. The extended period of proliferation of this callus indicated some instability in the compression system. Simultaneous with this proliferation, however, regressive changes occurred within the callus.

5. The intermediate fragment was rebuilt by simultaneous bone resorption and bone construction from the inside of the Haversian canal systems containing functioning vessels. A large part of the rebuilding process took place by means of cutting heads, which directly formed secondary osteones. The same process applied to the avascular marginal zone in the main frag-

ments and to the primarily formed bone in the fracture gap, in preparation for reorientation of the collagenous structures according to functional demands.

6. The osteotomy zones were rebuilt without any collapse and the intermediate fragment kept its size throughout the healing period.

7. Whether the endosteal-periosteal bone formation predominates over the intracanalicular bone formation in the gap would seem to depend upon the size of the avascular zones. Regeneration of secondary osteones with cutting heads is a slow rebuilding process and is therefore easily surpassed by endosteal and periosteal new bone formation if prerequisites for such bone formation exist.

8. An osteosynthesis plate gives the bone essential support, which can contribute to early regressive changes on reconstruction of callus and cortical bone. The bone will thus become adapted to functional demands, which is evident in the occurrence of an increased number of resorption cavities and big canals. This gives so called spongy transformation of the cortical bone.

## FOREWORD

There are few topics in medicine, that have attracted the interest of so many investigators as the physiological significance(s) of Vitamin D. However, in spite of extensive research and innumerable publications, knowledge concerning the mode of action of the vitamin on the calcium homeostasis of the body is still incomplete.

The complexity of the "simple question" how does vitamin D influence skeletal metabolism? defies a simple experimental solution and requires an integrated, multilevel approach. With this in mind the authors have during the last years tried to throw some light on the question by conducting a correlated series of experimental investigations. The study started in Chicago, Illinois, was continued in the Orthopaedic Research Laboratory in Uppsala and later in Umeå, Sweden. The results were discussed at each stage by the senior authors (J. A. S. and R. D. R.) and each step was planned in close collaboration.

The results of these studies reinforce certain previous findings under standard conditions not prevalent in the multitude of separate studies in separate laboratories by separate people in the past, and add new aspects on the mechanism of action of vitamin D on bone.

The publication of the different sections of the work in the form of a supplementum was chosen since it gives a more coherent survey of the results obtained.

The investigations were aided by grants from the U. S. Atomic Energy Commission, AT (11—1) 1601, the United States Public Health Service (N. I. H. 47153) and the Swedish Medical Research Council, which are gratefully acknowledged. The printing costs of this publication have been financed partially by a grant from the Swedish Medical Research Council (contract B 69-50 T-2954-01).

## INTRODUCTION

Rickets as a clinical entity was first reported in 1645 in a thesis by Whistler<sup>1)</sup> entitled "De morbo puerili Anglorum quem patrio idiomate indigenae vocant, The Rickets". A detailed description of the disease followed 5 years later by Glison (1650). Almost two centuries later Guerin (1838) was probably the first to produce rickets in puppies and suggested that rickets resulted from a faulty diet. The curative effect of cod liver oil in clinical rickets was pointed out by Trousseau (1865). Hopkins in 1912 first suggested that rickets was due to a dietary deficiency and the same year Funk (1912) propounded the "vitamin hypothesis" according to which the existence of separate anti-beriberi, anti-scurvy, anti-rachitic and anti-pellagra "vitamins" was postulated. Huld-schinsky (1919) showed that rickets could be cured by artificial light no less than by direct sunlight. Steenbock and his co-workers, in 1924, deduced that ultraviolet rays activated some vitamin precursors in the skin of the body or in the food. Hess and Weinstock (1924) confirmed this shortly afterwards. One year later a crude cholesterol fraction was isolated from cod-liver-oil, by the same authors, and it was thought to be the "anti-rachitic provitamin". The vitamin itself was isolated, in a pure state, from the irradiation products of ergosterol by Askew et al. in 1930 and by Windhaus et al. in 1932. The vitamin was first named vitamin D or calciferol. Ergocalciferol was later adopted as its official name. Two calcemic sterols have been prepared in crystalline form, namely vitamin D<sub>2</sub> or dihydrotachysterol-2 and vitamin D<sub>3</sub> or dihydrotachysterol-3, the latter showing a much higher effect in intestinal calcium absorption than the former. Excellent reviews on the mode of action of vitamin D are to be found in the literature (Nicolaysen and Eeg-Larsen 1953, Harris 1956, Weinmann and Sicher 1957, Firschein 1963, Frederick 1965, Harrison 1965/66, DeLuca 1967, 1969, Forbes 1967, Fourman et al. 1968, Norman 1968).

<sup>1)</sup> A reference list to this part of the work is to be found on page 82.

Vitamin D-deficiency in humans is a pathologic condition of early childhood. It is characterized clinically by decreased body growth, especially of the length of the long bones, softening of the bones of the skull (craniotobes), swelling of the costosternal synchondroses (rosary) as well as the metaphyseal parts of the long bones and radiologically by widening of the growth cartilage of the long bones with cup-shaped and irregular metaphyses. Blood chemistry is usually changed and is characterized by low levels of the serum phosphate and sometimes the serum calcium. The histological changes include increase in breadth of the zone of provisional calcification, inadequate mineralization of the newly formed bone matrix and appearance of osteoid tissue in the metaphyseal area. Renal disease and several other metabolic disturbances of totally different etiologies can give rise to a clinical picture resembling rickets.

By varying the amount of calcium and phosphate and depriving the diet of vitamin D a condition morphologically similar to that of human dietary rickets has been induced in experimental animals, providing the opportunity to study the various effects of vitamin D deficiency. The morphological studies of Dodds and Cameron (1934, 1938) and the biochemical studies of Nicolaysen and Jansen (1939) are classical works on experimental rickets in the rat. However, research regarding rickets is complicated by the fact that the condition can be produced in animals by vitamin D-deficiency in combination with varying changes of the Ca:P ratio of the diet. The fact that different species respond differently to these treatments is another factor complicating studies of experimental rickets.

The mode of action of vitamin D on the calcium homeostasis is not understood. It appears, however, that there are 4 main mechanisms of action of the vitamin, i. e.

- a) to stimulate the absorption of calcium and secondarily of phosphorus through the mucous membrane of the small intestine (Nicolaysen 1934, 1937, Nicolaysen and Eeg-Larsen 1953).
- b) to increase the reabsorption of inorganic phosphate (Harrison and Harrison 1941) and of calcium (Gran 1960) in the kidney tubules.
- c) to stimulate calcium release from mitochondria (Engstrom and DeLuca 1962, 1964 a, DeLuca et al. 1962).
- d) to influence the matrix of the bone to calcify or to resorb, an effect which is, however, controversial.

As to the mode of action of vitamin D on bone there are many diverging statements in the literature and its exact mechanism of action is still unknown. Numerous experiments have provided evidence supporting the following effects of vitamin D on bone metabolism:

- a) indirect on intestinal absorption of calcium and/or phosphorus (Harris and Innes 1931, Nicolaysen 1937).
- b) indirect on transport of calcium through the intestinal wall to the blood serum (Harris 1932, Schachter and Rosen 1959, Dowdle et al. 1960, Wasserman 1963).
- c) indirect on the parathyroid activity (Harrison et al. 1958, Rasmussen et al. 1963).
- d) indirect on alkaline phosphatase activity (Zetterström 1951).
- e) indirect on citrate metabolism (Schneider and Steenbock 1940, Harrison and Harrison 1952, Carlsson and Hollunger 1954, Neuman and Neuman 1958).
- f) direct on bone matrix (Gyorgy 1930, Schelling 1932 b, Fischman 1937, Nicolaysen and Jansen 1939, Carlsson and co-workers 1952, 1954, 1955, Nicolaysen and Eeg-Larsen 1953 and others) an effect which, however, is still disputed.

Decalcification of the long bones by large doses of vitamin D was demonstrated histologically by Gyorgy in 1930. The action of the vitamin on calcification of bone in human rickets was first attributed to promotion of the intestinal absorption of calcium and increase of the  $\text{Ca} \times \text{P}$  product in the serum, thus secondarily favoring deposition of new bone mineral. It was suggested that the defective calcification of bone in rickets depends on failure of intestinal absorption of calcium (Harris 1928, Wolbach and Bessey 1942). Nicolaysen and Jansen (1939), on the other hand, produced evidence in rats for a direct action of vitamin D on the matrix of the skeleton, although the calcifying effect of the vitamin on rachitic bone was attributed by these authors to its effect on serum phosphate. Defective synthesis of chondroitin sulphate by the hypertrophic cartilage in rachitic bone has been described, but it was found that vitamin D has no effect on the metabolism of this substance by these cells (Hjertquist 1964).

A local calcium mobilizing action of large doses of vitamin D on bone was postulated by Schelling (1932), Barnicott (1951) and others. Carls-

Vitamin D-deficiency in humans is a pathologic condition of early childhood. It is characterized clinically by decreased body growth, especially of the length of the long bones, softening of the bones of the skull (craniotobes), swelling of the costosternal synchondroses (rosary) as well as the metaphyseal parts of the long bones and radiologically by widening of the growth cartilage of the long bones with cup-shaped and irregular metaphyses. Blood chemistry is usually changed and is characterized by low levels of the serum phosphate and sometimes the serum calcium. The histological changes include increase in breadth of the zone of provisional calcification, inadequate mineralization of the newly formed bone matrix and appearance of osteoid tissue in the metaphyseal area. Renal disease and several other metabolic disturbances of totally different etiologies can give rise to a clinical picture resembling rickets.

By varying the amount of calcium and phosphate and depriving the diet of vitamin D a condition morphologically similar to that of human dietary rickets has been induced in experimental animals, providing the opportunity to study the various effects of vitamin D deficiency. The morphological studies of Dodds and Cameron (1934, 1938) and the biochemical studies of Nicolaysen and Jansen (1939) are classical works on experimental rickets in the rat. However, research regarding rickets is complicated by the fact that the condition can be produced in animals by vitamin D-deficiency in combination with varying changes of the Ca:P ratio of the diet. The fact that different species respond differently to these treatments is another factor complicating studies of experimental rickets.

The mode of action of vitamin D on the calcium homeostasis is not understood. It appears, however, that there are 4 main mechanisms of action of the vitamin, i. e.

- a) to stimulate the absorption of calcium and secondarily of phosphorus through the mucous membrane of the small intestine (Nicolaysen 1934, 1937, Nicolaysen and Eeg-Larsen 1953).
- b) to increase the reabsorption of inorganic phosphate (Harrison and Harrison 1941) and of calcium (Gran 1960) in the kidney tubules.
- c) to stimulate calcium release from mitochondria (Engstrom and DeLuca 1962, 1964 a, DeLuca et al. 1962).
- d) to influence the matrix of the bone to calcify or to resorb, an effect which is, however, controversial.

- b) vitamin D promotes the calcification of the bone matrix in rickets, probably secondarily,
- c) vitamin D in large doses has a calcium mobilizing effect on bone,
- d) vitamin D in physiological doses promotes the calcium mobilization from the bone in a direct way, an effect which is contested and
- e) the action of vitamin D on bone calcium metabolism is probably indirect.

Studies concerning the mode of action of vitamin D on bone calcium mobilization are complicated by the fact that parathyroid hormone has a known effect on calcium metabolism similar to that attributed to vitamin D.

The effect of parathyroid hormone on the mobilization of bone salt from the trabeculae of cancellous bone was demonstrated by McLean and Bloom (1941). Several other experimental studies provided further evidence for the action of the parathyroid extract on bone resorption (Barnicott 1948, Chang 1951, Grollman 1954, Greep and Kenny 1955, Gaillard 1955, 1957, Watanabee 1960, Raisz et al. 1961 and Goldhaber 1963) either indirectly through changes in the plasma level of inorganic phosphate (Albright et al 1948) or directly on the inorganic part of the bone (McLean and Urist 1955, Woods and Armstrong 1956 and Talmage and Elliot 1958) or on both the organic and inorganic part (Bronner 1960).

Work on the interaction between vitamin D and parathyroid hormone on calcium mobilization from bone goes back to the late twenties. It was observed that large doses of vitamin D given to hypocalcaemic dogs on low calcium diets, converted hypocalcemia to hypercalcemia, while corresponding doses failed to raise serum calcium levels in thyro-parathyroidectomized animals (Hess et al. 1928/29, Greenvald and Cross 1929). An opposite relation was reported several years later, i.e. lack of the calcium mobilising and hypercalcemic action of parathyroid extract in vitamin D deficient rats, unless the animals were pretreated with vitamin D (Harrison et al. 1958, Marnay and Raoul 1959, Marnay 1961) and it was, therefore, suggested that action of parathyroid hormone on mineral mobilization from bone requires the presence of vitamin D (Rasmussen et al. 1963). Other experimental studies provided, however, evidence that a definite increase in serum calcium occurs after administration of parathyroid extract to vitamin D deficient mice (Nichols et al. 1963), adult and young rats (Toverud 1964) and hens (Hertelendy and Taylor 1960).

son's work in 1952 and following years (1954, 1955) provided evidence that vitamin D in physiological doses favours the removal of lime salts from the bones. He stated that the effect of vitamin D on raising the serum calcium level and increasing growth and calcification of the skeleton were secondary to its primary effect on bone. These results were later confirmed by Nicolaysen and Eeg-Larsen (1953) and recently by Sankaran (1969). "Carlsson's effect" has, however, been contested by Migicovsky (1957). That high doses of vitamin D result in bone resorption is well documented by several experimental observations. Whether this effect of high vitamin D doses is due to a direct action on bone has been contested but seems fairly certain. However, whether physiological doses of vitamin D have this effect has been seriously contested.

During recent years the interest of several investigators has again been focused on the mode of action of vitamin D on the intestinal absorption of calcium. It is now believed that this vitamin induces the synthesis of the appropriate enzyme systems or the alteration of membrane structure necessary for calcium absorption (Norman 1966). Regarding the effect of vitamin D on bone calcification it has been stated that it seems unlikely that an additional effect of vitamin D at the calcification sites exists, but that the question remains still open (DeLuca 1967). Experimental data suggest, on the other hand, that vitamin D action on bone involves or requires a cellular component and it is not simply due to an acceleration of physicochemical exchange processes between crystal surface and extracellular fluid (Yuile et al. 1967). In studies on  $\text{Ca}^{45}$  absorption in the rachitic chick it was found that vitamin D exerts its action only after a lag time of several hours (Norman 1966). Evidence was also provided that vitamin D administration induces the formation or elaboration of a calcium binding factor by intestinal mucosa, and that this factor is a protein. The hypothesis that vitamin D acts as an initiator of enzyme synthesis in the intestinal mucosa was thus advanced (Wasserman and Taylor 1966). The work of DeLuca and co-workers (DeLuca 1969) during recent years has provided several evidence that 25-hydroxycholecalciferol is the metabolically active form of vitamin  $\text{D}_3$  and the conversion of the latter to the former requires about 6 hours, this providing another explanation for the lag time required for the action of vitamin D.

Summarizing the evidence for an action of vitamin D on bone the following statement may be made:

- a) absence of vitamin D is responsible for the defective calcification of the bone matrix in rickets,

# EFFECT OF VITAMIN D ON THYRO-PARATHYROIDECTOMIZED RATS

By

J. A. SEVASTIKOGLOU, M.D.

and

R. D. RAY, M.D., Ph.D.

It seems very likely that there is an interrelationship between parathyroid hormone and vitamin D on the mobilization of bone calcium. Several theories have been advanced to explain the nature of this interrelationship. It has been stated that parathyroid hormone and crystalline vitamin D<sub>2</sub> act "synergistically" to enhance bone resorption (Goldhaber 1963). It has also been stated that the action of vitamin D and parathyroid hormone are "additive" in respect to their effect on calcium metabolism in bone (Nichols et al. 1963). Most accepted is, however, the concept of the "permissive" action of vitamin D, according to which the effect of vitamin D is only that of permitting the circulating parathyroid hormone to exert its characteristic effect (Rasmussen and DeLuca 1963).

The series of investigations presented herewith was initiated to determine whether vitamin D has a direct action on bone calcium metabolism. Because of the interaction between vitamin D and parathyroid hormone the first experiment was designed to investigate the effects of large and physiological doses of vitamin D on thyro-parathyroidectomized young rats. A second experiment was carried out to determine to what extent parathyroid hormone, vitamin D and calcium are essential for survival in the rat. Reports regarding the effect of parathyroid hormone on mobilization of bone calcium in vitamin D deficient animals were not in agreement and hence a third investigation was carried out. The next experiment was undertaken to examine the effect of physiological doses of vitamin D on mobilization and/or uptake of calcium by bone in well defined *in vitro* experimental system in which there was virtual absence of interaction between vitamin D and other biological agents. The last study was carried out to study the effect of prolonged vitamin D deficiency on the composition of the diaphyseal cortical bone of young rats.

## EFFECT OF VITAMIN D ON THYRO-PARATHYROIDECTOMIZED RATS<sup>1)</sup>

By J. A. SEVASTIKOGLU, M. D. and R. D. RAY, M. D., Ph. D.

*It has been reported that large doses of vitamin D cause local mobilization of calcium from bone (Schelling 1932, Barnicott 1951). Carlsson and co-workers (1952 a, 1952 b, 1954, 1955) showed that young rats maintained on a low calcium, high phosphorus, vitamin D deficient diet, developed a low serum Ca level. When vitamin D was given to these animals in physiological doses, the serum calcium levels returned to normal. The authors concluded that "even in physiological doses, vitamin D has a marked stimulating influence on bone resorption". This effect, confirmed by Nicolaysen and Eeg-Larsen (1953) and by Sankaran (1969), has been, questioned by Migicovsky (1957).*

Parathyroid hormone apparently acts in similar fashion on bone calcium mobilization (McLean and Bloom 1937, 1941, Barnicott 1948, Gaillard 1955) even in minute amounts (Gaillard 1961).

The possibility of a relationship between these two agents in their action on bone has been suspected for a long time; in fact clinical parathyroid deficiency is traditionally treated by large doses of vitamin D. Harrison et al. (1958) and later Raoul and Marnay (1960) and Rasmussen et al. (1963) provided experimental evidence that the effect of parathyroid hormone on mobilization of bone mineral requires the presence of vitamin D. This, however, has been questioned by other investigators (Hertelendy and Taylor 1960, Nichols et al. 1963, Toverud 1964).

The effect of vitamin D on bone calcium in the absence of parathyroid hormone has been investigated earlier (Hess et al. 1928/29, Greenwald and Gross 1929, Schelling 1932 a, Asher and Jones 1933) but the reported results are not conclusive.

The purpose of this investigation was to study the effect of various doses of vitamin D on skeletal retention of  $\text{Ca}^{45}$  and the serum calcium level and specific activity in thyro-parathyroidectomized rats.

## EFFECT OF VITAMIN D ON THYRO-PARATHYROIDECTOMIZED RATS<sup>1)</sup>

By J. A. SEVASTIKOGLU, M. D. and R. D. RAY, M. D., Ph. D.

It has been reported that large doses of vitamin D cause local mobilization of calcium from bone (Schelling 1932, Barnicott 1951). Carlsson and co-workers (1952 a, 1952 b, 1954, 1955) showed that young rats maintained on a low calcium, high phosphorus, vitamin D deficient diet, developed a low serum Ca level. When vitamin D was given to these animals in physiological doses, the serum calcium levels returned to normal. The authors concluded that "even in physiological doses, vitamin D has a marked stimulating influence on bone resorption". This effect, confirmed by Nicolaysen and Eeg-Larsen (1953) and by Sankaran (1969), has been, questioned by Migicovsky (1957).

Parathyroid hormone apparently acts in similar fashion on bone calcium mobilization (McLean and Bloom 1937, 1941, Barnicott 1948, Gaillard 1955) even in minute amounts (Gaillard 1961).

The possibility of a relationship between these two agents in their action on bone has been suspected for a long time; in fact clinical parathyroid deficiency is traditionally treated by large doses of vitamin D. Harrison et al. (1958) and later Raoul and Marnay (1960) and Rasmussen et al. (1963) provided experimental evidence that the effect of parathyroid hormone on mobilization of bone mineral requires the presence of vitamin D. This, however, has been questioned by other investigators (Hertelendy and Taylor 1960, Nichols et al. 1963, Toverud 1964).

The effect of vitamin D on bone calcium in the absence of parathyroid hormone has been investigated earlier (Hess et al. 1928/29, Greenwald and Gross 1929, Schelling 1932 a, Asher and Jones 1933) but the reported results are not conclusive.

The purpose of this investigation was to study the effect of various doses of vitamin D on skeletal retention of  $\text{Ca}^{45}$  and the serum calcium level and specific activity in thyro-parathyroidectomized rats.

<sup>1)</sup> This investigation was aided by grant nr 47153 from the National Institutes of Health, U S Public Health Service and grants nr U-58, Y-171 and B-66-214 from the Swedish Medical Research Council

## MATERIALS AND METHODS

Twenty two young male Sprague-Dawley rats with a mean body weight of 75 gms were allocated in 3 groups. The rats of one group were to use as controls and those of the remaining two groups underwent thyro-parathyroidectomy 8 days before sacrifice. The rats of one of these two groups were given an excess of vitamin D. All rats were maintained on a standard laboratory ration containing 1.40 per cent calcium, 1.20 per cent phosphorus and the necessary amounts of vitamin D<sub>3</sub> (about 15 IU/gr diet). Food and tap water were provided *ad libitum* and the rats were housed under standard laboratory conditions.

*Thyro-parathyroidectomy* was performed 8 days before sacrifice under general ether anaesthesia. The thyroid together with both parathyroids were removed *in toto* at operation. The specimens were sectioned serially, stained with haematoxylin eosin and studied for histological evidence of the completeness of the operation.

*Excess of vitamin D* was administered by daily subcutaneous injections of 1 ml of vitamin D<sub>2</sub><sup>1)</sup> (10,000 I. U./ml) dispersion in saline for 4 consecutive days before sacrifice of the animals. The vitamin D solution was prepared daily.

*Isotope studies:* Six days before sacrifice all animals were injected intraperitoneally with 10  $\mu$ C of Ca<sup>45</sup> in 1 ml saline. After being fasted 24 hours the animals were sacrificed by bleeding from the abdominal aorta under ether anaesthesia. The blood was immediately centrifuged for 15 min. at 3,000 r. p. m. in a common laboratory centrifuge and the supernatant serum was pipetted into clean tubes and stored in the deep-freeze at -20° C until used. The hind legs of each animal were disarticulated at the knee joint and the diaphysis of both tibias of all rats were dissected free from soft tissues and periosteum. The epiphyses together with the epiphyseal cartilage plates were removed at the metaphyseal line.

The wet weights of the diaphyses were recorded. After dehydration of the bones overnight at 50° C the dry weight was determined and the bones were ashed in a muffle furnace at 700° C overnight. The ashed

<sup>1)</sup> Water Dispersable Vitamin D<sub>2</sub> (500,000 I. U. per gr) General Biochem. Co., Chagrin Falls, Ohio

bones were then weighed under standardized conditions, the specimens being enclosed in stoppered polyethylene vials. The water, organic and ash content of the tibiae were calculated as percentages of the wet weight. The ashed tibiae were processed to determine the specific activity by dissolving in 5 ml of a 5 per cent solution of concentrated HCl. After the samples were completely dissolved, the solution was diluted with distilled water to a final volume of 100 ml. A 2 ml aliquot was pipetted into a 25 ml polyethylene counting vial which was then filled with a gel scintillator. The samples were counted in a Packard Tri-carb liquid scintillation counter.

For determination of the  $\text{Ca}^{45}$  activity of the serum, 0.5 to 1.0 ml of serum was pipetted in the counting vials which were then filled with the gel scintillator and counted as above.

*The total specific activity of the bones/mg ash and of the serum/ml was calculated and expressed as a percentage of the injected isotope per gram body weight.*

*Serum calcium determinations were performed using an Ependorf flame photometer.*

## RESULTS

One thyro-parathyroidectomized rat died in tetany 24 hours after the operation and was excluded from the material.

Histological examination of the tissues removed at surgery revealed that both parathyroids were totally removed in all cases.

*The tibia weights were consistently lower in the thyro-parathyroidectomized rats when compared with the controls. The differences were somewhat more pronounced in thyro-parathyroidectomized rats maintained on normal doses of vitamin D than in those treated with excess vitamin D. However, the percentages of  $\text{H}_2\text{O}$ , organic material and ash showed no appreciable differences (Table I). The results of these studies were not analysed statistically.*

The bone specific activities of the thyro-parathyroidectomized rats given vitamin D in normal or excess amounts were somewhat higher than for the normal controls. There were, however, no significant differences in bone specific activity between the groups<sup>1)</sup> (Table II and Fig 1).

The serum specific activities of the thyro-parathyroidectomized rats receiving vitamin D in normal amounts were much lower than for the controls. Thyro-parathyroidectomized rats on high levels of vitamin D also had lower serum activity than normal rats. In the first instance the mean values were 27 per cent and in the second 12 per cent lower than the mean values for the controls (Table II, Fig. 1). These differences were, however, not significant.

<sup>1)</sup> The statistical treatment of the obtained results has been based on pair comparisons using the t-test

The results of the present study revealed that both normal and high levels of vitamin D administration failed to restore the serum calcium levels of thyro-parathyroidectomized rats. It must, therefore, be concluded that in the absence of the thyroid and parathyroids vitamin D did not have its characteristic hypercalcemic effect, indicating that the bone calcium mobilizing effect was not independent.

#### SUMMARY

Growing thyro-parathyroidectomized rats maintained on a high calcium, high phosphorus diet and normal amounts of vitamin D had no significant change in  $\text{Ca}^{45}$  retention by the skeleton. A decrease in serum specific activity was not statistically significant. There was, however, a significant decrease in the serum calcium 8 days after surgery.

Larger doses of vitamin  $\text{D}_2$  (10 000 IU) injected subcutaneously for 4 consecutive days also failed to raise the serum calcium levels of thyro-parathyroidectomized rats.

*The serum calcium content* was low in the thyro-parathyroidectomized rats of both groups compared to the normal controls and these differences were significant ( $p < 0.05$ ). There were no differences in serum calcium content between the thyro-parathyroidectomized rats of the two groups (Table II and Fig. 1).

## DISCUSSION

To remove the parathyroids a total thyro-parathyroidectomy was performed because it was found in pilot experiments that was almost impossible to remove the parathyroids of these small animals without resecting large parts of the thyroid at the same time. Histological studies revealed that with parathyroidectomy alone both parathyroids were completely removed in only 25 per cent of the cases. However, in removing the thyroid a new factor was introduced, i. e. the simultaneous elimination of thyroxin and hypocalcemic effect of calcitonin. Thus the results must be considered in light of both the thyroid and parathyroid deficiency invoked to these rats.

The results of the  $\text{Ca}^{45}$  studies revealed that thyro-parathyroidectomized rats maintained on adequate amounts of vitamin D had an insignificant change in bone specific activity. The pronounced decrease of the serum specific activity was not statistically significant. In contrast to these findings, the decrease in serum calcium content 8 days after thyro-parathyroidectomy was significant. These results confirm the effects of thyro-parathyroidectomy in vitamin D fed animals reported by Rasmussen et al. in 1963.

Vitamin D in doses of 10,000 IU daily for 4 consecutive days did not cause hypercalcemia in the thyro-parathyroidectomized rat. In other words injection of large doses of vitamin D failed to restore the disturbed calcium homeostasis.

These results confirm previous observations that large doses of vitamin D failed to raise the serum calcium level in thyro-parathyroidectomized dogs (Hess et al. 1928/29, Greenwald and Gross 1929, Asher and Jones 1933). However, it has been stated that the action of vitamin D of elevating the serum calcium level is not dependent on the parathyroids (Schelling 1932, Toverud 1964).

## EFFECT OF VITAMIN D AND CALCIUM ON SURVIVAL OF THE THYRO-PARATHYROIDECTOMIZED RAT<sup>1)</sup>

By J. A. SEVASTIKOGLU, M.D.<sup>2)</sup> and R. D. RAY, M.D., Ph.D.

The purpose of the following study was to determine the effect of dietary calcium on the survival of young thyro-parathyroidectomized rats, maintained on a vitamin D deficient, low phosphorus diet.

Carlsson (1952 a, 1952 b, 1954, 1955) reported that in young rats maintained on a low calcium, high phosphorus, vitamin D deficient diet with the parathyroid glands intact, vitamin D in physiological doses returned the serum calcium level to normal, presumably by mobilizing calcium from the skeleton. In an earlier study the authors found that either physiological or large doses of vitamin D failed to restore the serum calcium level to normal in young thyro-parathyroidectomized rats (Sevastikoglou and Ray 1970 a). The question thus arose as to whether young rats deprived of vitamin D, the thyroid and the parathyroids could survive when maintained on a low phosphorus and either a low or high calcium diet.

It has been reported that 7 to 11 weeks old parathyroidectomized rats can survive for 3 months when fed a high calcium, low phosphorus, vitamin D deficient diet (Asher and Jones 1933), but that fasting parathyroidectomized rats develop tetany and die within 24 hours (Jones 1938). It has also been reported that young rats on a phosphate rich, nearly calcium free ration die in less than 72 hours if both parathyroid hormone and vitamin D are lacking (Crawford et al. 1957). It has been maintained that parathyroidectomized vitamin D deficient rats can survive on a very low calcium diet, but that chicks with their parathyroids intact will die within a week when kept on a low calcium, vitamin D deficient diet (Migicovsky 1962).

<sup>1)</sup> This investigation was aided by research grants from the National Institutes of Health, United States Public Health Service (grant nr 47153) and from the Swedish Medical Research Council (grant nr U-58)

<sup>2)</sup> Former Research Associate, Department of Orthopaedic Surgery, University of Illinois, Chicago

vitamin D deficient high calcium diet (nr. 1) and the rats in group II were maintained on a vitamin D supplemented high calcium diet (nr. 4). At the end of the 4th post operative week each group of rats was subdivided, and one subgroup was continued on the same diet and the other was placed on a low calcium diet (no. 2 and 3 respectively).

Food and distilled water were allowed *ad libitum* and the rats were kept in darkness. The body weights were recorded at intervals.

## RESULTS

*Histological studies* showed that the thyroid and both parathyroids were completely removed in 60 cases. In four of the rats thyro-parathyroidectomy was successfully performed but because of technical problems the removal of the parathyroids could not be determined. These animals were included in the series.

The body weight changes for each experimental group are shown in Fig. 1 to 3. There were large variations during the experimental period.

FIG 1 Body weight and mortality rate of control rats maintained on vitamin D deficient diet. Upper 6-week old rats. Lower 4-week old rats. Dotted lines low calcium vitamin D deficient diet. Circles indicate the number of deaths.

FIG. 2. Body weight and mortality of thyro-parathyroidectomized rats maintained on vitamin D supplemented diet. Upper: 6-week old rats. Lower: 4-week old rats. Dotted lines: low calcium, vitamin D supplemented diet. Circles indicate the number of deaths.

\* Because of a mistake, the rats of this group received a high phosphorus diet for an unknown period of time after the 31st day.

FIG. 3. Body weight and mortality of thyro-parathyroidectomized rats maintained on vitamin D deficient diet. Upper 6-week old rats. Lower 4-week old rats. Dotted lines: low calcium, vitamin D supplemented diet. Circles indicate the number of deaths.

**Mortality.** 13 of the 64 thyro-parathyroidectomized rats died in tetany within 48 hours after the operation, 11 in the younger age group. Two more of the young rats died for reasons not connected with the surgery. Thus 49 rats remained for inclusion in the experimental final results. All of the thyro-parathyroidectomized rats on the vitamin D deficient diet, regardless of the calcium content, died within 6 to 11 weeks (Fig. 1). The younger rats died earlier than the older ones. Although some deaths occurred in the two other experimental groups, (Figs. 2 and 3) the difference between the mortality rate of the thyro-parathyroidectomized rats maintained on the vitamin D deficient diet compared with the mortality rate for the other two experimental groups was significant ( $p < 0.01$ )<sup>1)</sup> (Table II).

Several of the thyro-parathyroidectomized animals developed signs of tetany soon after surgery but after the 7th postoperative day the signs of tetany disappeared. Deaths during the subsequent experimental period was preceded by loss of body weight and development of cachexia. Blood diarrhoea was present in several rats of the 3rd group before death.

<sup>1)</sup> The hypergeometric distribution was used in this case, computing the probability of a result, at least as extreme as this one, by combinatorial test

TABLE II Distribution of the material and deaths during the experimental period.

Experimental groups	Age of the rats (weeks)	No. of rats	Deaths during the experimental period
I	6	15	1
Rats on Vit D deficient diet	4	16	5
II	6	14	0
Thyro-parathyroidectomized rats on Vit D suppl diet	4	11	7
III	6	15	15
Thyro parathyroidectomized rats on Vit III deficient diet	4	11	11

## DISCUSSION

The reason for removing the thyroid in order to secure complete removal of both parathyroids has been discussed earlier (Sevastikoglou and Ray 1970 a). Thus the results of this experiment must also be evaluated in light of the deficiency of both the thyroid and parathyroids.

The large variations in body weight of rats maintained on vitamin D deficient and supplemented diets and the small differences observed between thyro-parathyroidectomized and non operated animals might suggest that the vitamin rather than thyroid or parathyroid deficiency was responsible for the loss of body weight. However, reduction in the calcium content of the diet in thyro-parathyroidectomized rats also resulted in loss of body weight regardless of the amount of vitamin D in the diet. The control rats on the other hand increased in body weight when the calcium content of the vitamin D deficient diet was decreased. No explanation has been found for this observation.

As pointed out earlier it has been reported that 7 to 11 week old thyro-parathyroidectomized rats can survive for about 3 months if they are maintained on a high calcium, low phosphorus, vitamin D deficient diet (Asher and Jones 1933). The results of the present study indicated however, that 4 to 6 week old thyro-parathyroidectomized rats maintained on a low phosphorus vitamin D deficient diet did not survive more than 6 to 8 weeks regardless of the calcium content of the diet.

If the diet was supplemented with adequate amount of vitamin D the thyro-parathyroidectomized rats did survive the experimental period. This suggests that vitamin D administration in the absence of the thyroid and parathyroid glands can permit survival of rats regardless of the level of calcium in the diet. The mechanism of action of vitamin D under these circumstances is difficult to ascertain since the serum calcium levels were not determined, and the role played by the absence of the thyroid was unknown.

## SUMMARY

Four and 6-week old thyro-parathyroidectomized rats did not survive when deprived vitamin D. Death occurred as a rule 6 to 8 weeks after the onset of vitamin D deficiency regardless of whether the diet contained adequate amounts of calcium or not.

Young rats with intact thyroid and parathyroid glands survived at least 8 weeks when maintained on a vitamin D deficient, low calcium diet.

Young thyro-parathyroidectomized rats maintained on a vitamin D supplemented diet with either a high or low calcium content also survived for the same experimental period.

# EFFECT OF PARATHYROID HORMONE IN THE ABSENCE OF VITAMIN D

By

J. A. SEVASTIKOGLU, M. D.

and

R. D. RAY, M. D., Ph. D.

## EFFECT OF PARATHYROID HORMONE IN THE ABSENCE OF VITAMIN D<sup>1)</sup>

By J. A. SEVASTIKOGLOU, M.D. and R. D. RAY, M.D., Ph.D.

Although some relationship between the action of vitamin D and parathyroid hormone on the skeleton has been suspected for many years, the exact mechanism by which they affect calcium homeostasis is not known. Furthermore there is no agreement as to whether the hypercalcemic action of parathyroid hormone is dependent on the presence of the vitamin. It has been reported that parathyroid hormone fails to raise the serum calcium level in vitamin D deficient rats (Crawford et al. 1957, Harrison et al. 1958, Marnay and Raoul 1959, Marnay 1961). Rasmussen et al. (1963) confirmed that parathyroid hormone failed to correct the hypocalcemia of vitamin D deficient rats, although when given in massive doses (2,000 I. U.) a rise in serum calcium levels did occur. The authors concluded that action of parathyroid hormone on mobilization of calcium from bone requires the presence of vitamin D. It has also been reported that a definite increase in serum calcium levels occurs following administration of parathyroid extract to vitamin D deficient hens (Hertelendy and Taylor 1960) mice (Nichols et al. 1963) adult and young rats (Toverud 1964) and dogs (Ney et al. 1965).

The purpose of the following study was to determine the effects of various dose levels of parathyroid hormone on vitamin D deficient rats.

### MATERIALS AND METHODS

Twenty six young male Sprague Dawley rats with initial body weight of approximately 75 gms were divided at random into 4 experimental groups of 6 to 8 rats per group. Three groups were maintained for 27 days on a high calcium, low phosphorus, vitamin D deficient diet<sup>2)</sup>. The

<sup>1)</sup> This investigation was aided by grant nr 47153 from the National Institutes of Health, U. S. Public Health Service and grants nr U-58, Y-171 and B-66-214 from the Swedish Medical Research Council

<sup>2)</sup> Brunius D-40 diet, composed by ground yellow corn 86 per cent; powdered egg albumin 10 per cent, iodized NaCl 1 per cent and calcium carbonate 3 per cent.

## EFFECT OF PARATHYROID HORMONE IN THE ABSENCE OF VITAMIN D<sup>1)</sup>

By J. A. SEVASTIKOGLOU, M. II and R. D. RAY, M. D., Ph. D.

Although some relationship between the action of vitamin D and parathyroid hormone on the skeleton has been suspected for many years, the exact mechanism by which they affect calcium homeostasis is not known. Furthermore there is no agreement as to whether the hypercalcemic action of parathyroid hormone is dependent on the presence of the vitamin. It has been reported that parathyroid hormone fails to raise the serum calcium level in vitamin D deficient rats (Crawford et al. 1957, Harrison et al. 1958, Marnay and Raoul 1959, Marnay 1961). It has also been reported that a definite increase in serum calcium levels occurs following administration of parathyroid extract to vitamin D deficient hens (Hertelendy and Taylor 1960) mice (Nichols et al. 1963) adult and young rats (Toverud 1964) and dogs (Ney et al. 1965).

The purpose of the following study was to determine the effects of various dose levels of parathyroid hormone on vitamin D deficient rats.

### MATERIALS AND METHODS

Twenty six young male Sprague Dawley rats with initial body weight of approximately 75 gms were divided at random into 4 experimental groups of 6 to 8 rats per group. Three groups were maintained for 27 days on a high calcium, low phosphorus, vitamin D deficient diet<sup>2)</sup>. The

<sup>1)</sup> This investigation was aided by grant nr 47153 from the National Institutes of Health, U. S. Public Health Service and grants nr U-58, Y-171 and B-66-214 from the Swedish Medical Research Council

<sup>2)</sup> Brunia D 40 diet, composed by ground yellow corn 86 per cent, powdered egg albumin 10 per cent, iodized NaCl 1 per cent and calcium carbonate 3 per cent.

calcium content of the diet was 1.33 per cent and the phosphorus content 0.28 per cent. The fourth group of rats was given the same diet though supplemented with 6 IU of vitamin D<sub>2</sub><sup>1)</sup> per gr diet. Food and distilled water were given *ad libitum* and the animals were in a darkened room.

The rats of the first (control), second and third experimental groups had intact parathyroid glands. The rats in the third group were treated by excess of parathyroid extract and the rats of the fourth group were thyro-parathyroidectomized 8 days before sacrifice.

*Excess parathyroid hormone* was given to the animals in form of subcutaneous injections of 1 ml (100 IU) parathyroid extract<sup>2)</sup> daily for 4 consecutive days before sacrifice.

*Thyro-parathyroidectomy* was performed under ether anaesthesia. The completeness of the operation was determined as previously described (Sevastikoglou and Ray 1970 a).

*Isotope studies:* all rats were given 10  $\mu$ C of Ca<sup>45</sup> intraperitoneally 6 days before sacrifice. The specific activity of the ashed tibias was determined as described earlier (Sevastikoglou and Ray 1970 a). The specific activity of the bones/mg ash and of the serum/ml was calculated and expressed as a percentage of the dose of isotope per gram body weight.

*The body weights* were recorded at the beginning of the experiment, the day of isotope injection and the day of sacrifice.

*Roentgenograms* of the femurs and the paws of all the rats were taken to determine the effect of the diets on skeletal development.

*Serum calcium determinations* were performed using an Ependorf flame photometer.

## RESULTS

One thyro-parathyroidectomized rat died in tetany within 24 hours of surgery and was excluded from the experiment. The remaining experimental and control rats survived the period of observation.

Histological examination of the tissues removed from the rats that underwent thyro-parathyroidectomy revealed that both parathyroids were totally removed in every case.

1) Water Dispersable Vitamin D<sub>2</sub> (500 000 IU/gr), General Biochemicals Co., Chagrin Falls, Ohio.

2) Parathyroid extract, Eli Lilly and Co., Inc.

*Roentgenologic examination* of the paws and femurs of the rats on the vitamin D deficient diet revealed characteristic signs of rickets including increased width of the epiphyseal cartilage plates and irregularity of the metaphyseal areas. Control rats fed the same diet supplemented with vitamin D did not show signs of rickets but there was narrowing of the epiphyseal cartilage plates.

The changes in body weight for the rats in the four groups are summarized in Table I. All rats showed a slight increase in weight during the experimental period. There was a 35 per cent slower gain in weight for vitamin D deficient rats treated with parathyroid extract. There were no appreciable differences in body weight gains between the remaining experimental groups and the control rats maintained on the vitamin D supplemented diet.

The weights and the composition of the tibias of the rats in the different groups showed no appreciable differences compared to the control animals (Table I).

The specific activities of the tibias of all experimental groups were lower than for the control rats but the observed differences were not statistically significant<sup>1)</sup> (Table II and Fig. 1).

The serum specific activities showed large variations between the control and the experimental groups. Thus vitamin D deficient rats with either normal parathyroid function or excess parathyroid extract had 15 and 20 per cent higher mean values respectively as compared to the values for the control rats. The mean calcium specific activity of vitamin D deficient thyro-parathyroidectomized rats was 21 per cent lower than for the controls. The values showed, however, a large spread within each group and the differences between groups again were not significant (Table II and Fig. 1).

<sup>1)</sup> The statistical treatment of the obtained results has been based on pair comparisons using the t-test.

FIG. 1 a) Bone  $\text{Ca}^{45}$  specific activity, b) serum  $\text{Ca}^{45}$  specific activity, c) serum calcium content for the three experimental groups and the controls (left). 0 indicates a normal level, + excess, - deficiency.

The serum calcium content was somewhat lower in rats maintained on the vitamin D deficient diet with normal parathyroid function but the difference was not significant. Rats on the vitamin D deficient diet receiving excess parathyroid extract showed higher and thyro-parathyroidectomized vitamin D deficient rats showed lower serum calcium levels compared to the control rats (Table II and Fig. 1). The observed differences were significant ( $p < 0.05$  and  $< 0.01$  respectively).

## DISCUSSION

The data on body weights and the tibia weights for the animals in the different experimental groups showed slight differences compared to the control rats and need not be discussed.

As mentioned earlier, previous reports regarding the action of parathyroid hormone on the serum calcium level of vitamin D deficient animals have been questioned. The observation that parathyroid hormone fails to raise the calcium levels in rats deprived of vitamin D (Crawford et al 1957, Harrison et al. 1958, Marnay and Raoul 1959, Marnay 1961,

Rasmusson et al. 1963) has also been challenged by the observation that administration of parathyroid extract to vitamin D deficient animals raises the serum calcium levels (Hertelendy and Taylor 1960, Nichols et al. 1963, Toverud 1964, Ney et al. 1965). The results of the present investigation support the latter observations.

As an explanation of the discrepancy between reported experimental results regarding the effect of parathyroid hormone on vitamin D deficient animals, Rasmussen et al. (1963) suggested that failure to observe dependence of parathyroid action upon vitamin D might be attributed to incomplete vitamin D deficiency. These authors were able to demonstrate that the responsiveness of bone mineral mobilization to parathyroid hormone requires only minute amounts of vitamin D (0.3 IU per rat). The vitamin D deficiency of this diet was not extreme, only sufficient to produce radiographic evidence of skeletal changes corresponding to that seen in severe deficiency. The rats used in Toverud's experiments (1964) were, however, carefully prepared to meet the requirements of extreme vitamin D deficiency of approximately the same order of magnitude as that secured by Rasmussen et al. (1963). Furthermore, the observation that vitamin D deficient rats with intact parathyroids failed to have normal serum calcium levels suggests that parathyroid hormone, at least in normal amounts, does not influence serum calcium levels in the case of incomplete vitamin D deficiency. This suggests that a hypercalcemic action of parathyroid hormone is present in vitamin D deficient rats only when given in large doses. This is, on the other hand in agreement with Rasmussen et al. observation (1963) that massive doses of parathyroid hormone, 2,000 I, U., did result in a rise of the serum calcium levels in vitamin D deficient rats. It seems, therefore, improbable that such minute difference in the degree of vitamin D deficiency, if any, could alone be responsible for the extreme variations in the results and other possible explanations for the divergence in results should be sought.

It has been reported that an increase in the Ca and P content of the diet from 0.12 to 0.24 per cent results in a significant rise in Ca and P levels of the serum of the same order of magnitude as that produced by vitamin D when added to the low mineral diet (Harrand et al. 1966). The Ca: P ratio in Toverud's stock diet was 0.52: 0.54 and in the present experiment 1.33: 0.28. The ratio in Harrison et al. experiment was 0.7: 0.56 and in Rasmussen et al. experiment 4 different diets were used with Ca: P ratios of 0.47: 0.3, 0.2: 0.3, 1.2: 0.1 and 0.02: 0.02. It is, therefore, obvious that variations in the Ca: P ratio in the diets may at least be partly responsible for the variations in reported results.

The results of the isotope studies showed that excess parathyroid extract given to vitamin D deficient rats resulted in only an insignificant decrease of isotope retention by the skeleton. This might indicate either that the calcium needed for normalization of the serum calcium values was not of such a magnitude to influence significantly the  $\text{Ca}^{45}$  retention of the bone, or that calcium was provided from extra skeletal sources as for example increased intestinal absorption or reabsorption in the kidneys. As to the serum specific activity, an increase of 20 per cent compared to the control group, occurred with excess parathyroid extract in the vitamin D deficient rats but this difference was not statistically significant. It is possible that the large spread of some of the values in this group of animals was the reason for the discrepancy.

A significant decrease of the serum calcium levels was observed in the thyro-parathyroidectomized vitamin D deficient rats. In an earlier experiment it was found that young rats treated in an identical way die within 60 days, regardless if adequate calcium was provided in the diet or not (Sevastikoglou and Ray 1970 b). No reason for the death of these rats could be advanced. The results of the present experiment suggest that prolonged severe hypocalcemia and failure of the body to regulate calcium homeostasis in the absence of both parathyroid hormone and vitamin D, might be, at least a contributory cause to the death of those animals.

#### SUMMARY

Young rats maintained on a high calcium, low phosphorus, vitamin D deficient diet, with normal parathyroid function showed no changes in the retention of  $\text{Ca}^{45}$  by the skeleton, the serum specific activity or calcium content as compared to control rats maintained on the same diet supplemented with vitamin D.

Similar rats treated with subcutaneous injections of 100 IU parathyroid extract for 4 consecutive days before sacrifice showed a significant increase in the serum calcium level. The increase in serum specific activity was not statistically significant. A slight but insignificant decrease of isotope retention by the skeleton was also observed.

When thyro-parathyroidectomy was performed in vitamin D deficient rats there was a pronounced drop of the serum specific activity and serum calcium content but only the latter was statistically significant.

These results indicate that although normal levels of parathyroid hormone do not affect the serum calcium content of vitamin D deficient rats, excess parathyroid extract given to such rats results in a significant increase in the serum calcium level.

# EFFECT OF VITAMIN D ON BONE CALCIUM METABOLISM IN VITRO

By

J A SEVASTIKOGLU, M D

and

R. D RAY, M D, Ph D

## EFFECT OF VITAMIN D ON BONE CALCIUM METABOLISM IN VITRO<sup>1</sup>

By J. A. SEVASTIKOGLU, M. D. and R. D. RAY, M. D., Ph. D.

The aim of the following study was to determine whether vitamin D in moderate doses has a direct effect on uptake and/or release of calcium by bone maintained *in vitro*.

In 1932 Schelling stated that vitamin D in large doses accelerated the mobilization of calcium from bone. Barnicott (1951) implanted calvaria bone from young rats together with crystals of vitamin D into the brains of adult animals and described local bone resorption. Goldhaber (1963) maintained mice calvaria in tissue culture and found that the addition of vitamin D accelerated resorption. In all these studies very high levels of vitamin D were used.

Carlsson and co-workers (1952 a—1952 b, 1954, 1955) demonstrated that rats maintained on a low Ca, low vitamin D diet regained normal serum calcium levels when given vitamin D in physiological doses and concluded from this that vitamin D accelerated bone resorption. The observations of Carlsson were confirmed by Nicolaysen and Eeg-Larsen (1955) and most recently by Sankaran (1969). However, Sankaran also found that these animals had a significant increase in urinary calcium output as well as reduction in bone ash content. He pointed out, however, that it was impossible to conclude from *in vivo* studies whether the response was due to a direct action of vitamin D on bone. Migicovsky (1957) took exception to Carlsson's conclusions stating that "vitamin D affects the accretion rate, which in turn could bring about an increase in the resorption rate per bone" and that "it cannot be stated whether the action of the vitamin D on the bone is direct or indirect". It has been stated that the action demonstrated by Carlsson and Lindquist (1955) of physiological doses of vitamin D on the skeleton may not be direct, but could be mediated through the parathyroids with failure of calcium mobilization from the skeleton until the vitamin was administered (Harrison 1964) and that the bone mineral mobilization in response to parathyroid hormone requires minute amounts of vitamin D (Rasmussen and DeLuca 1963).

<sup>1</sup> This investigation was aided by grant nr 47153 from the National Institutes of Health, United States Public Health Service and grant U 58 from the Swedish Medical Research Council.

## MATERIAL AND METHODS

Two experiments were conducted: the first on *release* of  $\text{Ca}^{45}$  from bone to the medium and the second on *uptake* of  $\text{Ca}^{45}$  by bone from the medium. For each experiment six-week old, Long Evans rats were allocated to two groups. The first group was fed a high calcium, low phosphorus, vitamin D deficient diet (Steenbock and Black 1925) for 18 days. The second group was fed the standard laboratory ration. Chemical determinations of the Ca and P content of the diets showed that the vitamin D deficient diet contained 2.33 per cent Ca and 0.28 per cent P. The respective figures for the standard diet were 2.32 per cent and 1.48 per cent.

*Incubation medium:* Two types of media were used (NCTC-109 Evans 1956 a and 1956 b)<sup>1)</sup>: Vitamin D was omitted from one. The other contained 1 mg of vitamin  $\text{D}_2$  per liter<sup>2)</sup>, dissolved in 4 ml of 95 per cent ethanol.

In the studies on *release* of calcium from bone each animal was injected intraperitoneally with 10  $\mu\text{C}$   $\text{Ca}^{45}$  three days prior to sacrifice. No radioactive isotopes or streptomycin were added to the medium.

In studies on *uptake* of calcium by bone 0.033  $\mu\text{C}$   $\text{Ca}^{45}$  per ml, and 0.05 mg streptomycin per ml were added to the medium.

*Preparation of the samples for incubation:* After sacrifice by ether, the rats were depilated and bathed for a short while in an antiseptic solution. The hind legs were then disarticulated at the hip joint. Under sterile conditions the diaphysis of each tibia was dissected free from soft tissues and periosteum, and the epiphyses together with the epiphyseal cartilage plates were removed at the metaphyseal line. Each bone was split longitudinally, the marrow was carefully removed and the bone fragments washed in warm nutrient medium to remove adherent soft tissues and blood. The size of the fragments varied but their thickness as a rule did not surpass 0.5 mm. The fragments from the one tibia were transferred to a 30 ml plastic test tube, and 5 ml of the first type of medium were pipetted into the tube. The fragments from the contralateral tibia of the same animal<sup>3)</sup> were placed in another test tube and

1) The media were prepared and delivered in 100 ml sterile vials by Grand Island Biological Company, Grand Island, N Y

2) General Biochemicals Co., Chagrin Falls, Ohio

3) The wet-, dry-, and ash weights as well as the  $\text{Ca}^{45}$  specific activity of the tibias of the same animals were studied in pilot experiments. Minor differences observed between the values of the two tibias were not statistically significant

the same amount of the second medium was added. The tubes were sealed with rubber stoppers and placed in a roller tube apparatus, in an incubator at 37° C for 72 hours.

In the *uptake* experiment, in addition to living bone, killed bone fragments were also maintained in the culture medium in a parallel series of experiments. The fragments were boiled for 15 minutes in saline and then incubated. The killed samples served as controls for the viability of the living specimens.

*Preparation of the samples for counting:* At the end of 72 hours the bone fragments were removed from the incubation tubes, weighed and placed in a muffle furnace at 700° C overnight for ashing and the ash weight determined. The ashed bone fragments were processed for specific activity determinations as described earlier (Sevastikoglou and Ray 1970 a).

Determination of the specific activity of the medium was performed at the end of incubation and after removal of the bone fragments from the tubes. Three ml of the solution were pipetted into plastic counting vials which were filled with gel scintillator and counted in a liquid scintillation counter. The specific activities of the samples were calculated as follows: a) for the *release* experiment as counts per minute per 5 ml medium expressed as a percentage of the total (bone and medium) activity and b) and for the *uptake* experiment as counts per minute per mg ash weight of the incubated bone.

*Studies of bone viability* Determinations of the pH of the medium before and at the end of incubation (initial and final pH) as well as of blank samples incubated for 72 hours in the absence of bone, were performed. Furthermore, the pH of the medium in which fragments of killed bone were incubated for 72 hours was also determined.

Sections of living and killed bone, before and after 72 hours incubation, were examined histologically after haematoxylin eosin staining.

Analysis of variance was used for statistical evaluation of the results.

## RESULTS

Bacterial contamination of the cultures was rare. When this occurred, the affected cultures were excluded from the study.

The initial and final pH of the culture media are given in Table I.

TABLE I. pH variations of the medium. The values represent the means for at least 3 pH determinations followed by the standard deviation of the mean.

	Release experiment		Uptake experiment		
	Living bone samples	Blanks	Living bone samples	Dead bone samples	Blanks
Initial pH	$7.37 \pm 0.03$	$7.37 \pm 0.03$	$7.82 \pm 0.07$	$7.82 \pm 0.07$	$7.82 \pm 0.07$
Final pH	$7.39 \pm 0.02$	$8.47 \pm 0.12$	$7.68 \pm 0.01$	$8.14 \pm 0.04$	$8.42 \pm 0.07$

*Histological studies:* Sections of boiled bone showed a very intense eosinophilic staining throughout. Few empty lacunae were present. At high magnification shrinkage of the osteocyte nuclei was apparent. Sectioned specimens both before and after incubation had exactly the same appearance and no microscopic changes in the structure of the bone occurred during incubation. The living bone specimens showed normal staining characteristics. Sections of fresh non-incubated bone had a normal histological appearance. However, incubated specimens showed scattered empty lacunae as well as areas with cell occupied lacunae. The nuclei of the bone cells were round and had a healthy appearance. The living bone areas were by far more abundant and larger than the devitalized bone areas.

*The specific activity of the medium in the release experiment* (Table II) was found to be higher with bone from the vitamin D deficient, than from the normal rats, the difference being highly significant. The minor differences between the specific activities of the medium containing vitamin D and deprived of vitamin D were not significant.

TABLE II Release experiment. The medium  $\text{Ca}^{45}$  specific activity after 72 hours of incubation. The values represent the means of 7 determinations followed by the standard deviation of the mean.

		Vitamin D deficient medium	Vitamin D containing medium	p
$\text{Ca}^{45}$ specific activity per 5 ml medium as percentage of the total (bone + medium) activity	Vitamin D deficient rats	$3.584 \pm 0.331$	$3.610 \pm 0.295$	$> 0.05$
	Normal rats	$1.180 \pm 0.050$	$1.109 \pm 0.067$	$> 0.05$
	p	$< 0.001$	$< 0.001$	

TABLE III. Uptake experiment. The bone  $\text{Ca}^{45}$  specific activity after 72 hours of incubation. The values represent means of 7 determinations followed by the standard deviation of the mean.

Bone $\text{Ca}^{45}$ specific activity (counts per min per mg ash)	Vitamin D deficient rats	Vitamin D deficient medium	Vitamin D containing medium	P
	Normal rats	$146.02 \pm 4.85$	$142.44 \pm 5.42$	$> 0.05$
		$96.10 \pm 2.36$	$90.90 \pm 3.31$	$> 0.05$
		$< 0.001$	$< 0.001$	

Bone derived from vitamin D deficient animals showed a significantly higher uptake of  $\text{Ca}^{45}$  *in vitro* than bone from normal rats (Table III). Again there was no variance in specific activity between samples incubated in a vitamin D free and vitamin D containing medium.

#### DISCUSSION

The question of whether the "living" bone fragments were really viable is of paramount importance in interpreting the results. It has been reported that the *in vitro* uptake of  $\text{Sr}^{90}$  by devitalized bone is equal to that of living bone. Mobilization of  $\text{Sr}^{90}$  is, on the other hand much higher from living than from devitalized bone (Ray et al. 1955).

Several reports indicate that embryonic bone cultivated in protein free synthetic media survives with morphological and metabolic evidence of activity (Wolff et al. 1953, Kieny 1955, Biggers et al. 1957, 1961, Lengenmann 1962, Gorham and Waymouth 1965). The medium used in these earlier experiments was similar to the medium used in the present study.

The final pH of the medium used to maintain the "living" bone showed a slight shift from the initial pH and was obviously lower than the final pH of the blanks. The final pH of the samples in which killed bone was incubated was considerably higher than the initial pH, almost as high as the final pH of the blanks. This might be explained by the assumption that some metabolic activity of "living" bone preserved the final pH of the buffered medium at the initial level. When no cellular activity was involved the final pH shifted to an alkaline level, as observed in the blanks and the case of incubated samples of killed bone. In metabolic studies of "living" bone fragments *in vitro* using no buffered (Basset and Nordin 1959) or buffered media (Shartum and Nichols 1961) only minor changes in the pH were recorded after 48 or 16 hours respectively. The

solubility of bone mineral was found to be independent within the observed pH range (Shartum and Nichols 1961).

Histological study of the boiled bone showed that the fragments were devitalized before incubation and that no morphological changes occurred during incubation. Contrary "living" bone fragments revealed a healthy appearance after incubation throughout the section. Minor populations of dead cells merging into areas of bone of normal appearance were also present. Death of certain portions of the incubated bone fragments was expected as a result of uneven thickness of the fragments and hence uneven conditions of nutrition.

The pH and the morphological studies suggest that the bone fragments remained viable during incubation.

*In vitro* investigations concerning the effect of vitamin D on bone have been carried out earlier by several authors. Shipley et al. (1925) and Howland (1925) reported that epiphyseal cartilage from rachitic rats placed in the serum of rachitic rats did not calcify, but did calcify when placed in serum from non-rachitic rats. Fischmann (1937) observed that osteogenic tissue cultivated in blood serum derived from normal roosters developed and calcified well, but if serum from vitamin D deficient animals was used osteoid tissue and abnormal non-calcified cartilage formed. Rat calvaria maintained in a medium composed of chicken plasma and embryo extract as well as horse serum showed marked bone resorption when large doses of dihydrotachysterol and crystalline vitamin D<sub>2</sub> or D<sub>3</sub> were added. The simultaneous addition of parathyroid extract (0.1 U per ml) and crystalline vitamin D<sub>2</sub> (0.01 mg per ml) resulted in "synergistic enhancement of bone resorption" (Goldhaber 1963). Mice calvaria from vitamin D deficient animals pretreated with vitamin D or parathyroid extract were maintained in buffered Krebs-Ringer solution for 16 hours. Studies of the mobilization of calcium, phosphorus and citrate by bone led to the conclusion that vitamin D appears to modify the metabolism of bone fragments *in vitro* in a fashion similar to that following treatment with parathyroid hormone. It was, therefore, stated that is likely that vitamin D and parathyroid hormone are "additive in respect to their actions on calcium metabolism of bone" (Nichols et al. 1963). A similar effect of vitamin D on rat calvaria maintained *in vitro* and pretreated with vitamin D was reported later by Au and Bartter (1966). It has been reported, on the other hand, that vitamin D has no effect on calcification of hypertrophic cartilage maintained *in vitro* (Robinson 1934) and that the addition of vitamin D in alcoholic or aqueous solution or sera from animals treated with large doses of vitamin D in

embryonic rat bone cultures maintained on a mixture of equal parts of serum and modified Eagle's medium did not stimulate bone resorption directly (Raisz 1965). The present results are thus in agreement with those of Robison and Raisz but disagree with the results of the other authors referred on above.

An explanation for the divergence in the reported effect of vitamin D on the resorption of bone *in vitro* may be the existence or not of parathyroid hormone on the used systems. As mentioned elsewhere there are several studies suggesting an interrelationship between vitamin D and parathyroid hormone in their action on bone (Harrison et al. 1958, Marnay and Raoul 1959, Marnay 1961, Newman and Dowse 1961, Rasmussen et al. 1963). There are also reports that such an interaction does not really exist (Hertelendy and Taylor 1960, Nichols et al. 1963, Toverud 1964) and it has been stated that the fact that the controversy exists requires that the question remains open (Munson et al. 1963). If such an interrelationship exists the experimental systems used by Goldhaber, Nichols et al. and Au and Bartter do not eliminate the possible intervention of parathyroid hormone. In his tissue culture media Goldhaber used biological substances such as plasma, embryo extract and serum, which probably contain some parathyroid hormone. Furthermore the vitamin D doses used by Goldhaber were by far larger, approximately 100 times, than those used in the present study. Nichols et al. and Au and Bartter in their experiment pretreated the vitamin D deficient animals with vitamin D before the bones were removed and maintained in the *in vitro* system. A prior interaction between vitamin D and parathyroid hormone, therefore, can not be excluded. The failure of vitamin D to mobilize calcium despite the presence of serum and hence parathyroid hormone in the used culture medium in Raisz's experiment makes however, this possibility questionable.

The question arises as to whether vitamin D was really active in the vitamin D supplemented medium, since it has been demonstrated that the activity of the vitamin may vary considerably under different experimental conditions such as temperature or oxygen or the presence or absence of lipids and/or proteins in the solution (Evans 1964, Chen and Lane 1965). There is no way to give a direct answer to this question with the available data, but the method of preparation of the vitamin D is considered to be compatible with tissue culture work. Evans and co-workers (1964) reported that bone cells derived from human femur could be kept alive in NC TC 109 culture medium containing 0.25 mg/liter vitamin D<sub>2</sub> for 761 days.

It seems more appropriate to correlate the divergence in the reported results to the possibility of vitamin D to be converted to its metabolite, described by Lund and DeLuca (1966), now known as 25-hydroxycholecalciferol. It has been shown most recently that addition of this metabolite stimulates definitely the resorption of fetal rat bone cultured in a chemically defined medium (Trummel et al. 1969). According to DeLuca (1969) "it appears almost certain" that 25-hydroxycholecalciferol is the metabolically active form of vitamin D and that the liver is necessary to activate vitamin D by converting it to its 25-hydroxy-derivative. However, this hypothesis too can not explain the results reported by Goldhaber. It is, therefore, obvious that there is no way to give a satisfactory explanation for the divergence in the reported results regarding the action of vitamin D on bone resorption *in vitro*.

Another observation made in this study was that the *in vitro* metabolic rate of  $\text{Ca}^{45}$ , both mobilization and uptake, was significantly higher in bone derived from vitamin D deficient rats than from normal animals, regardless of whether vitamin D was added to the medium or not. It has been reported that the uptake of calcium tracers by bone derived from rachitic animals *in vivo*, compared with that from animals treated with vitamin D, is the same (Harrison and Harrison 1950) or decreased (Greenberg 1945, Carlsson 1951, Hurni et al. 1957) and compared to normal animals is either equal (Harrison and Harrison 1950) or decreased (Jones and Copp 1951, Hurni et al. 1957, Bohr 1961). Furthermore, it has been found that during the first hours after intravenous administration of radiocalcium or strontium, both normal and rachitic bones take up almost equal amounts of isotope. After twenty-four hours the retention by rachitic bones was half that of normal bone (Bohr 1964). This difference in isotope retention by bone in normal and vitamin D deficient rats has been attributed to an increased excretion in the urine of the rachitic animals, mainly because of the higher specific activity of radiocalcium in the blood (Bohr 1964).

In the present study however, bone from rats maintained on the vitamin D deficient diet showed a significantly higher mobilization of isotope than normal bone and furthermore, bone from vitamin D deficient rats maintained in a  $\text{Ca}^{45}$  containing medium showed also a significantly higher isotope uptake than normal bone. These observations indicate that the metabolic activity of bone derived from vitamin D deficient rats has a significantly higher calcium turnover rate than bone derived from normal animals and as expressed in this experiment, increased mobilization as well as uptake of  $\text{Ca}^{45}$ . The latter fact is in agreement with reports

that bone from rachitic rats takes up more vitamin D than from normal stock rats (Kodiçek and Thompson 1965, Neville and DeLuca 1966) but disagrees with the statement that "rachitic bone takes up as much minerals as the normal bone when identical amounts of Ca and P are supplied to it" (Nicolaysen and Eeg-Larsen 1953). It must be pointed out in this context that the composition of the diet given to the rats of the two groups was different with regard to the Ca and P content, which might be the reason of the different metabolic activity of the bones.

#### SUMMARY

Bone fragments from vitamin D deficient and normal young rats were incubated for 72 hours in a NCTC-109 synthetic culture medium, with or without supplemental vitamin D<sub>2</sub> (0.1 mg %).

Maintenance of physiologic pH by "living" bone fragments confirmed histologic evidence of viability of the explants after the 72 hour experimental period.

Studies of the calcium metabolism by means of Ca<sup>45</sup> either injected to the rats prior to sacrifice or alternatively added to the medium indicated that:

- a) Ca<sup>45</sup> uptake by and release from bone obtained from vitamin D deficient and normal rats was not affected by the addition or not of vitamin D in the *in vitro* system used in this experiment.
- b) the release and uptake of Ca<sup>45</sup>, *in vitro* was significantly higher for bone from vitamin D deficient than from normal rats.

It seems more appropriate to correlate the divergence in the reported results to the possibility of vitamin D to be converted to its metabolite, described by Lund and DeLuca (1966), now known as 25-hydroxycholecalciferol. It has been shown most recently that addition of this metabolite stimulates definitely the resorption of fetal rat bone cultured in a chemically defined medium (Trummel et al. 1969). According to DeLuca (1969) "it appears almost certain" that 25-hydroxycholecalciferol is the metabolically active form of vitamin D and that the liver is necessary to activate vitamin D by converting it to its 25-hydroxy-derivative. However, this hypothesis too can not explain the results reported by Goldhaber. It is, therefore, obvious that there is no way to give a satisfactory explanation for the divergence in the reported results regarding the action of vitamin D on bone resorption *in vitro*.

Another observation made in this study was that the *in vitro* metabolic rate of  $\text{Ca}^{45}$ , both mobilization and uptake, was significantly higher in bone derived from vitamin D deficient rats than from normal animals, regardless of whether vitamin D was added to the medium or not. It has been reported that the uptake of calcium tracers by bone derived from rachitic animals *in vivo*, compared with that from animals treated with vitamin D, is the same (Harrison and Harrison 1950) or decreased (Greenberg 1945, Carlsson 1951, Hurni et al. 1957) and compared to normal animals is either equal (Harrison and Harrison 1950) or decreased (Jones and Copp 1951, Hurni et al. 1957, Bohr 1961). Furthermore, it has been found that during the first hours after intravenous administration of radiocalcium or strontium, both normal and rachitic bones take up almost equal amounts of isotope. After twenty-four hours the retention by rachitic bones was half that of normal bone (Bohr 1964). This difference in isotope retention by bone in normal and vitamin D deficient rats has been attributed to an increased excretion in the urine of the rachitic animals, mainly because of the higher specific activity of radiocalcium in the blood (Bohr 1964).

In the present study however, bone from rats maintained on the vitamin D deficient diet showed a significantly higher mobilization of isotope than normal bone and furthermore, bone from vitamin D deficient rats maintained in a  $\text{Ca}^{45}$  containing medium showed also a significantly higher isotope uptake than normal bone. These observations indicate that the metabolic activity of bone derived from vitamin D deficient rats has a significantly higher calcium turnover rate than bone derived from normal animals and as expressed in this experiment, increased mobilization as well as uptake of  $\text{Ca}^{45}$ . The latter fact is in agreement with reports

that bone from rachitic rats takes up more vitamin D than from normal stock rats (Kodicek and Thompson 1965, Neville and DeLuca 1966) but disagrees with the statement that "rachitic bone takes up as much minerals as the normal bone when identical amounts of Ca and P are supplied to it" (Nicolaysen and Eeg-Larsen 1953). It must be pointed out in this context that the composition of the diet given to the rats of the two groups was different with regard to the Ca and P content, which might be the reason of the different metabolic activity of the bones.

### SUMMARY

Bone fragments from vitamin D deficient and normal young rats were incubated for 72 hours in a NCTC-109 synthetic culture medium, with or without supplemental vitamin D<sub>2</sub> (0.1 mg %).

Maintenance of physiologic pH by "living" bone fragments confirmed histologic evidence of viability of the explants after the 72 hour experimental period.

Studies of the calcium metabolism by means of Ca<sup>45</sup> either injected to the rats prior to sacrifice or alternatively added to the medium indicated that:

- a) Ca<sup>45</sup> uptake by and release from bone obtained from vitamin D deficient and normal rats was not affected by the addition or not of vitamin D in the *in vitro* system used in this experiment.
- b) the release and uptake of Ca<sup>45</sup>, *in vitro* was significantly higher for bone from vitamin D deficient than from normal rats.

# CHEMICAL STUDIES OF CORTICAL DIAPHYSEAL BONE DURING VITAMIN D DEFICIENCY IN THE RAT<sup>1</sup>)

By S.-O. HJERTQUIST, M.D., E. BERGQUIST, M.D.  
and J. A. SEVASTIKOGLOU, M.D.

The effect of vitamin D on bone metabolism in general and on the defective calcification of newly formed rachitic bone matrix in particular, is not fully understood. The results of earlier experimental studies of vitamin D deficiency and bone metabolism have not been consistent and indeed have often been contradictory. It is known that young animals maintained on a vitamin D deficient, low phosphorus diet develop pronounced morphological changes comparable to those observed in human rickets, with accompanying disturbances in the inorganic composition of the skeleton. However, studies of the chemical composition of the organic component of rachitic bone are few and almost exclusively confined to the epiphyseal cartilage and metaphyseal bone. (Harris 1956, Irving 1957, Folis 1958, 1960, Engfeldt and Hjertquist 1960, Fourman et al. 1968).

It has been reported that the hexosamine content of epiphyseal cartilage of rats with healing rickets is decreased compared with rachitic cartilage (Dikshit 1959). A slight increase in hexosamine content of rachitic chicken cartilage 48 hours after administration of vitamin D has also been reported (Cipera et al. 1960). In the latter case no changes in the ash content was found. Studies of acetone dried epiphyseal cartilage powder from normal and rachitic puppies as well as from puppies with healing rickets revealed that rachitic cartilage had a higher content of glycosaminoglycans than normal calculated per organic dry weight. Healing rachitic and rachitic cartilage did not show any significant differences (Hjertquist 1964 a). On the other hand no conclusive differences were found in total hexosamine concentration on the basis of organic dry weight or the concentration of various glycosaminoglycans comparing mineralised and non mineralised epiphyseal cartilage zones obtained by microdissection of freeze dried material from normal and healing rachitic cartilage of puppies (Hjertquist 1964 b).

<sup>1</sup> This investigation was aided by grants (nos 19 X-69-02, K 68-12 X-540-04 and B 69-12 X 540-06 A) from the Swedish Medical Research Council

The purpose of the following investigation was to determine whether there were any changes in the organic content of the skeleton and in particular in the glycosaminoglycan and hydroxyproline content of diaphyseal cortical bone during various stages of vitamin D deficiency in young rats.

## MATERIAL AND METHODS

Ninety eight male, weanling albino rats of the Sprague Dawley strain with a mean initial body weight of 38.5 gms were used. The animals were allocated at random to two groups, the first of 48 rats was maintained on the test diet<sup>1)</sup> and the second of 50 rats was used as a control group on the test diet supplemented with cod liver oil, 6—7 IU of vitamin D<sub>3</sub> per gm diet. The stock diet contained 1.33 per cent calcium and 0.28 per cent phosphorus. All animals were housed under standard laboratory conditions but without exposure to sun light. The vitamin D deficient rats were given deionized water and the control animals tap water. Food and water were given *ad libitum*. Five to 10 rats from each experimental group were sacrificed at weekly intervals up to 6 weeks. The body weight of the rats was recorded weekly.

After sacrifice by ether the rats were x-rayed. One radius from each was used for histological study (haematoxylin-eosin, toluidine blue and azan stains).

*Chemical analysis of the diaphyseal bone:* Both humeri and one radius of the rats were dissected free of soft tissue and periosteum. The epiphyses and the metaphyseal parts were removed with a fine band-saw. The diaphyseal cortical cylinders were split and the marrow removed. The bone fragments were then dehydrated for 2 days with several changes of acetone and air-dried. The fragments were crushed and pulverized with a Wiley laboratory mill, using a 60 mesh sieve. Since the amount of bone for the control rats was small and insufficient for individual analyses it was necessary to pool the bones for 6 to 9 rats from each group for chemical analyses.

<sup>1)</sup> Brunus D-40 diet, composed by ground yellow corn 86, powdered egg albumin 10, calcium carbonate 3 and iodized NaCl 1 per cent

The total hexosamine content was determined by the Elson and Morgan reaction, as modified by Antonopoulos et al. (1964) and described in detail earlier (Hjertquist and Vejlens, 1968, Larsson and Vejlens 1969). About 4 mg of bone powder were hydrolyzed in 1 ml of 6 M HCl in stoppered test-tubes (Quickfit MF 24/1/5) on a boiling water bath for 8 hours. After evaporation *in vacuo*, over sodium hydroxide pellets, in a desiccator, the residue was dissolved in 0.5 ml distilled water. This solution was used for the determinations. The values were expressed per total dry weight and per organic dry weight, i. e. after correction for the amount of calcium salts present in the acetone dried bone powder as hydroxyapatite.

The hexosamine corresponding to CPC precipitable glycosaminoglycans was determined as described earlier (Hjertquist and Vejlens 1968, Larsson and Vejlens 1969). Briefly about 10 mg bone powder was digested in stoppered test tubes (Quickfit MF 24/1/5) using 3 ml of digestion mixture (0.01–0.05 ml recrystallized papain suspension, Worthington added to 10 ml of a water solution containing EDTA and cystein HCl at a concentration of 0.05 M and 0.005 M, respectively, pH adjusted to 7.0 by 2.0 M NaOH), for 6 hours in a water bath at 65 °C. After digestion 2.0 ml 1 % (w/v) cetylpyridinium chloride (CPC) were added to the samples and the mixture was left over night. The precipitate was recovered by centrifugation at 3200 g and hexosamine determinations were performed on the precipitate by the Elson and Morgan reaction described above. The values obtained indicated the CPC precipitable glycosaminoglycans, largely chondroitin sulphate (Hjertquist and Vejlens 1968, Larsson and Vejlens 1969). These values were expressed both per total dry weight and per organic dry weight of the bone powder.

The hydroxyproline was determined on bone powder hydrolysates by the method of Neuman and Logan (1950). The ratios of total hexosamine and the glycosaminoglycans to hydroxyproline were calculated.

Microfractionation of the glycosaminoglycans was performed on pooled acetone dried bone powder from rats on the vitamin D deficient diet for 1 to 5 weeks and from rats maintained on the vitamin D containing diet for 1 to 6 weeks, as described earlier by Larsson and Vejlens (1969). In this way the solubility profiles of the chondroitin sulphate CP-complex and hence information of the molecular weight distribution of this polysaccharide was obtained.

*Calcium in bone powder* was determined by flame photometry using an ion exchange technique (Dowex 50H<sup>+</sup>, 200—400 mesh), according to the method of Strandh (1960) scaled up; 1.0 mg bone powder was used with 4×20 mm columns, 2.0 ml washing water and 3.0 ml eluting solution (4.0 M HCl).

Because the material for chemical analyses was pooled statistical treatment of the data was not possible. The results are, therefore, recorded as observed differences between mean values. In addition the slopes for the mean values were determined by graphs.

## RESULTS

Fourteen deaths occurred during the study, 6 in the treated and 8 in the control group.

*The body weight* of the rats of both groups remained almost constant up to 3rd week of observation and showed a slight successive increase later (Table 1).

*Roentgenologic examination* of the rats on the vitamin D deficient diet disclosed characteristic signs of rickets after 3rd week. Rats maintained on the same diet supplemented with vitamin D, showed narrowing of the epiphyseal cartilage, but no other abnormalities.

*Histological examination* of the distal radial epiphyseal cartilage of the vitamin D deficient rats, showed after 1 week characteristic morphological changes, which were fully developed after 2 to 3 weeks on the diet. The changes were identical to those described in earlier reports on the pathology of vitamin D deficiency in rats, by Dodds and Cameron (1934) and others. The epiphyseal cartilage plates of rats maintained on the vitamin D supplemented diet were normal in appearance except for slight narrowing of width. The diaphyseal cortical bone was extremely thin in both groups of rats. No osteoid seams were found on the examined specimens of cortical bone from vitamin D deficient and control rats.

The total hexosamine concentration per total dry weight of the bone powder was consistently higher for rats maintained on the vitamin D deficient diet, than the corresponding values for the pooled bone powder from the control rats. As the time of observation progressed there was a clear tendency for a decrease in the values in both series (Table I and Fig. 1).

FIG. 1 The total hexosamine content of the cortical bone powder ( $\mu\text{g/mg}$  total dry weight):  $\bullet-\bullet$  vitamin D deficient rats,  $\circ-\circ$  control rats. The values for the control rats obtained from pooled material from each group.

The hexosamine corresponding to CPC precipitable glycosaminoglycans per total dry weight of the bone powder showed small variations and was almost constant during the period of observation in the vitamin D deficient rats. In rats maintained on the test diet supplemented with vitamin D, there was a slight though definite decrease in the slope during the time of observation and the values were consistently lower than the corresponding values for the vitamin D deficient rats (Table I and Fig. 3).

FIG. 3 The glycosaminoglycan hexosamine content of the cortical bone powder (µg/mg total dry weight) —●— vitamin D deficient rats, —○— control rats. The values for the control rats obtained from pooled material from each group.

The total hexosamine concentration per organic dry weight of the bone powder from rats maintained on the vitamin D deficient diet were consistently higher than the corresponding values obtained from material pooled from the control rats. There was clear decrease in the slope in the latter case (Table I and Fig. 2).

FIG. 2. The total hexosamine content of the cortical bone powder ( $\mu\text{g}/\text{mg}$  organic dry weight).  $\bullet$ — $\bullet$ : vitamin D deficient rats;  $\circ$ — $\circ$  control rats. The values for the control rats obtained from pooled material from each group.

The solubility profiles of the CP-complex of the chondroitin sulphate for pooled bone powder from the rats of the 2 experimental groups were remarkably similar. The maximal peak was observed at 0.50 M  $\text{MgCl}_2$  and the first and last fractions were eluted with 0.25 and 0.75 M  $\text{MgCl}_2$  respectively in both cases (Fig. 5).

FIG. 5 Solubility profiles of the CP-chondroitin sulphate complexes of the cortical bone powder. Per cent hexosamine per 0.05 M  $\text{MgCl}_2$  as a function of the concentration of the eluting solution. The amount of hexosamine is expressed as per cent of total hexosamines eluted from the microcolumns. Upper: vitamin D deficient rats. Lower: control rats.

The glycosaminoglycans content per organic dry weight of the bone powder from the vitamin D deficient rats remained almost constant during the period of observation. For the rats maintained on the vitamin D containing diet, the values were consistently lower than the corresponding values for the vitamin D deficient rats, and plotted with time there was a clear decrease in the slope for the mean values (Table I and Fig. 4).

FIG 4. The glycosaminoglycans hexosamine content of the cortical bone powder ( $\mu\text{g}/\text{mg}$  organic dry weight).  $\bullet\text{---}\bullet$  vitamin D deficient rats,  $\circ\text{---}\circ$  control rats. The values for the control rats obtained from pooled material from each group.

The hydroxyproline content per organic dry weight of the bone powder showed also increased values after the 3rd week of observation both for the vitamin D deficient and for the control rats. The values for the vitamin D deficient rats were, with one exception, lower than the corresponding values for the control rats (Table I and Fig. 7).

FIG. 7 The hydroxyproline content of the cortical bone powder ( $\mu\text{g}/\text{mg}$  organic dry weight)  $\bullet$ — $\bullet$  vitamin D deficient rats,  $\circ$ — $\circ$  control rats. The values for the control rats obtained from pooled material from each group.

The hydroxyproline content per total dry weight of the bone powder from rats on the vitamin D deficient diet showed an increase toward the later stage of the experimental period. The values obtained from the vitamin D deficient rats were consistently lower than the corresponding values for the controls (Table I and Fig. 6).

FIG. 6. The hydroxyproline content of the cortical bone powder ( $\mu\text{g}/\text{mg}$  total dry weight).  $\bullet$ — $\bullet$ : vitamin D deficient rats,  $\circ$ — $\circ$ : control rats. The values for the control rats obtained from pooled material from each group.

The calcium content of the bone powder expressed as a fraction of the total dry weight was constant during the period of observation for the vitamin D deficient rats. The calcium content of the bone from the control rats was irregular during the period of observation and showed no consistent tendency when plotted. The observed differences between the corresponding values for the 2 experimental groups were negligible (Table 1 and Fig. 10).

## DISCUSSION

Studies of the calcium content of the acetone dried powder derived from cortical bone revealed no appreciable differences between vitamin D deficient rats and rats on the same diet supplemented with adequate amounts of vitamin D.

It has been reported that the calcium content of the tibia is lower in rachitic chicks than in controls given the same rachitogenic diet supplemented with vitamin D (Migicovsky and Belanger 1962). The difference between these and the present results might be attributed except that the

The ratios of total hexosamine and glycosaminoglycans to the hydroxyproline content of the cortical bone powder decreased gradually during the experimental period in both groups. This ratio was lower in the vitamin D deficient group at all time intervals (Table I and Figs. 8 and 9).

## SUMMARY

The glycosaminoglycans, hydroxyproline and calcium content of acetone dried powder of the cortical diaphyseal bone from weanling albino rats maintained for 6 weeks a) on a high calcium, low phosphorus, vitamin D deficient diet and b) on the same diet supplemented with adequate amounts of vitamin D were determined.

The calcium content of the acetone dried cortical bone powder showed no appreciable differences between the two groups.

The hydroxyproline content of the acetone dried bone powder were lower for the vitamin D deficient rats than for the control animals.

The total hexosamine and the glycosaminoglycans hexosamine components were higher in the vitamin D deficient than in the control rats, regardless of whether the fractions were expressed in terms of total dry weight or organic dry weight of the bone powder.

The solubility properties of the chondroitin sulphate of the pooled bone powder from vitamin D deficient and from control rats were remarkably similar, indicating no difference in molecular weight of this polysaccharide.

These results suggest that in rats on a high calcium, low phosphorus diet, vitamin D deficiency leads to a profound change of the organic composition of preformed cortical bone, but not the degree of calcification.

mineral composition of the used diets was different in the two experiments and that animals of different species were used, also to the fact that whole bone and not cortical diaphyseal bone alone was used in the former experiment.

It has also been reported that the calcium content of normal and healing rachitic epiphyseal growth cartilage of dog is higher than that of rachitic animals (Hjertquist 1964 a).

In the light of these observations it seems reasonable to assume that the epiphyseal growth cartilage and the whole bone, including the new-formed metaphyseal cancellous bone, fails to fully calcify when the animals are maintained on a vitamin D deficient diet but that, the calcium content of the previously formed diaphyseal cortical bone remains unchanged, at least during the first 6 weeks on the vitamin D deficient diet. On the other hand the results of this study revealed that the hydroxyproline content of the acetone dried bone powder was lower in vitamin D deficient rats than in control animals. The opposite relation was obtained with the total hexosamine and the glycosaminoglycans hexosamine regardless of whether the results were expressed in term of total dry weight or organic dry weight of the bone powder. Even the ratios of total hexosamine to hydroxyproline and glycosaminoglycans to hydroxyproline were consistently higher in vitamin D deficiency. As mentioned earlier it has been reported that the hexosamine content of the epiphyseal cartilage is decreased (Dikshit 1959) or increased (Cipera et al. 1960) in healing rickets, while no differences were observed as to the glycosaminoglycans content (Hjertquist 1964 a). There have been no previous reports concerning the glycosaminoglycans content of rachitic diaphyseal cortical bone.

The solubility properties of the CP-complex of the chondroitin sulphate of the pooled bone powder from vitamin D deficient rats and from control rats showed no differences, indicating that the molecular weight distribution of the chondroitin sulphate of the cortical diaphyseal bone was essentially the same in the 2 groups of animals.

The results of this study indicate that young rats maintained on a vitamin D deficient diet for up to 6 weeks did not show any changes in the degree of calcification of preformed diaphyseal cortical bone. On the other hand the organic fraction of the bone was profoundly affected with a decrease in hydroxyproline content and an increase in total hexosamine and glycosaminoglycan content. The changes in glycosaminoglycan content of the bone were quantitative and there were no differences in the molecular weight distribution of the chondroitin sulphate.

## SUMMARY

The glycosaminoglycans, hydroxyproline and calcium content of acetone dried powder of the cortical diaphyseal bone from weanling albino rats maintained for 6 weeks a) on a high calcium, low phosphorus, vitamin D deficient diet and b) on the same diet supplemented with adequate amounts of vitamin D were determined.

The calcium content of the acetone dried cortical bone powder showed no appreciable differences between the two groups.

The hydroxyproline content of the acetone dried bone powder were lower for the vitamin D deficient rats than for the control animals.

The total hexosamine and the glycosaminoglycans hexosamine components were higher in the vitamin D deficient than in the control rats, regardless of whether the fractions were expressed in terms of total dry weight or organic dry weight of the bone powder.

The solubility properties of the chondroitin sulphate of the pooled bone powder from vitamin D deficient and from control rats were remarkably similar, indicating no difference in molecular weight of this polysaccharide.

These results suggest that in rats on a high calcium, low phosphorus diet, vitamin D deficiency leads to a profound change of the organic composition of preformed cortical bone, but not the degree of calcification.

## GENERAL DISCUSSION AND CONCLUSIONS

The relation between vitamin D deficiency and the characteristic morphological changes in growing long bones is well established. Such changes have been induced in dogs (Mellanby 1918, 1919, 1925 and others) in chicks (Wanscher 1939 and others) in rats (McCollum et al. 1921, Sherman and Pappenheimer 1921 and others) as well as in rabbits, guinea pigs, pigs, calves and silver foxes to mention a few (Nicolaysen and Feg-Larsen 1953). The condition induced by vitamin D deficiency in experimental animals correspond to that observed in human rickets to such a degree that it has been stated: "Experimental rickets in animals duplicates completely the spontaneous disease in man and animals" (Wolbach and Bessey 1942). This may be true regarding the morphological changes but it is very doubtful that it is similarly true with regard to calcium kinetics, the blood serum changes and bone chemistry. The results of experimental studies in these respects are controversial and inconclusive. The divergencies may be attributed to one or more of the following factors, i. e.:

- a) the experimental animal,
- b) the duration and degree of the vitamin deficiency,
- c) the composition of the diet, principally with regard to calcium and phosphorus content

There is a marked difference in species response to the vitamin D (Rasmussen and Deluca 1963). It can be assumed, however, that the biochemical role of vitamin D, is the same in all species (Migicovsky and Belanger 1962). Since the clinical features of rickets in the dog, chicken and rat are similar to man (Nicolaysen and Feg-Larsen 1953) and calcium metabolism in rat is similar to man (Nicolaysen and Feg-Larsen 1953, Bronner and Lemaire 1969) it has been assumed that the two systems are comparable. The rat, therefore, has been the animal of choice in experiments on calcium metabolism and hence vitamin D deficiency.

Disagreement in the reported results regarding, for example, effect of parathyroid hormone on mobilization of the bone calcium in the absence of vitamin D in rats, has been attributed to the degree of vitamin deficiency in the different experiments (Rasmussen et al. 1963). However, the degree of vitamin D deficiency may not be the only factor responsible for the divergence in results (Sevastikoglou and Ray 1970c). Maintenance of animals on a vitamin D deficient diet for a sufficiently long period of time is necessary for a clearcut effect, as demonstrated in the present

studies. Thus, it was observed that while characteristic morphological changes were present in the growth cartilage plates after 1 week on a vitamin D deficient diet clearcut differences in the chemical composition of the skeleton were not present until the 3rd week (Hjertquist et al. 1970).

Studies of experimental vitamin D deficiency in the rat are further complicated by the fact that this species develops rachitic changes only when the Ca:P ratio of the diet is also modified (Pappenheim and Sherman 1921, Forbes 1967). It has been reported that a disorder simulating rickets can be produced in growing rats by a pure deficiency of phosphorus even in the presence of adequate amounts of vitamin D (Querido 1935, Freeman and McLean 1941, Coleman et al. 1950). It has also been reported that young animals develop skeletal changes typical of rickets upon specific calcium deficiency (Park et al. 1922, Hess 1929, Carttar et al. 1950, Engfeldt et al. 1962, Gershon-Cohen et al. 1962, McClendon and Blaustein 1965). These and other observations have cast doubts on the importance of vitamin D in mineral metabolism of the rat. On the other hand it has been reported that vitamin D is essential for calcium homeostasis in the albino rat even if the animal is fed a diet adequate in calcium and with a suitable ratio of Ca to P (Harrison et al. 1958). It has been stated that calcium and phosphorus content of the diet must be taken into account, in any experiment involving vitamin D deficiency in the rat (Nicolaysen and Eeg-Larsen 1953). It has been further stated that the reaction to vitamin D varies with the mineral composition of the diet (Migicovsky and Emslie 1947) and that in the absence of vitamin D the addition of minerals to the diet results in a rise in the serum Ca and P of the same order as that produced by the vitamin when added to a low mineral diet (Harrand et al. 1966, 1968). By comparison of the effect of diets of different compositions Ray et al. (1956) observed that a low-phosphorus diet displayed the more profound effect on strontium mobilization and skeletal mineralization in young rats. These observations and others have led to the statement that "it is necessary to distinguish between vitamin D deficiency and rickets particularly as regards the rat. Although the two are often synonymous they are not always so" (Rasmussen and DeLuca 1963). Thus, standardized dietary conditions are essential in studies of vitamin D deficiency in the rat. It would appear that differences in dietary composition rather than the degree of vitamin D deficiency may account for the differences in results in otherwise similar experiments, a fact already noted by Shelling (1932 a) in studies on the effects of parathyroidectomy in the rat. It is amazing that experimental

reports lack detailed descriptions of the diets, a fact also pointed out earlier (Rasmussen and DeLuca 1963, DeLuca 1967).

In the present experiments young growing rats from two different strains were used, i.e., Long Evans and Sprague Dawley. The rats were of approximately the same age and initial body weights. No special care was taken to obtain animals from strains maintained previously on low vitamin D diets but maintenance of the animals on the vitamin D deficient diet was regarded as sufficiently long, i.e., 3 weeks or more. In spite of the fact that each experiment was carried out with a specific purpose and not as a part of a prospective project, the diets were very similar with only variations related to the nature of the individual study and or the place where the investigation was carried out. The main features involved in the experimental conditions are summarized in Table 1.

TABLE 1 The main experimental conditions of the present studies.

Exp nr	Strain Age Initial body weight	Composition of the diets per dry weight			Duration of Vitamin D deficiency

In the present experiments young growing rats from two different strains were used, i. e., Long Evans and Sprague Dawley. The rats were of approximately the same age and initial body weights. No special care was taken to obtain animals from strains maintained previously on low vitamin D diets but maintenance of the animals on the vitamin D deficient diet was regarded as sufficiently long, i. e., 3 weeks or more. In spite of the fact that each experiment was carried out with a specific purpose and not as a part of a prospective project, the diets were very similar with only variations related to the nature of the individual study and/or the place where the investigation was carried out. The main features involved in the experimental conditions are summarized in Table I.

TABLE I The main experimental conditions of the present studies

Exp nr	Strain Age Initial body weight	Composition of the diets per dry weight			Duration of Vitamin D deficiency
		Ca %	P %	Vitamin D IU/gr diet	
1	Sprague Dawley approx 5 weeks old 75 gms	I 1.40	1.20	Optimal <sup>1)</sup>	—
2	Long Evans	I 2.33	0.28	—	Throughout the exp — " —
	a) 4 weeks old 62 gms	II 0.83	0.28	—	
	b) 6 weeks old 106 gms	III 0.83	0.28	5 IU <sup>2)</sup>	
		IV 2.33	0.28	5 IU	
3	Sprague Dawley approx 5 weeks old 75 gms	I 1.33	0.28	—	27 days
		II 1.33	0.28	II IU	—
4	Long Evans	I 2.32	1.48	Optimal <sup>3)</sup>	—
	a) 4 weeks old 63 gms				
	b) 3 weeks old 48 gms	II 2.33	0.28	—	18 days
5	Sprague Dawley 3 weeks old 39.5 gms	I 1.33	0.28	—	1-6 weeks
		II 1.33	0.28	6 IU	—

<sup>1)</sup> Standard laboratory ration for rats from Ewos Co., Södertälje, Sweden  
About 15 IU vitamin D/gr diet

<sup>2)</sup> The necessary amount of vitamin D for the rat depends on the mineral composition of the diet and is about 3 IU/gr diet daily (McCon 1949)

<sup>3)</sup> Standard laboratory ration for rats from Ralston Purina Co., St. Louis, Miss.  
About 14 IU vitamin D/gr diet

The experiments were primarily designed to answer the question of whether or not vitamin D has a direct effect on bone metabolism. Possible interrelations between vitamin D and parathyroid hormone were the subject of special studies in this context, although some of the other aspects of the vitamin such as its role in survival and its effect on the chemistry of cortical diaphyseal bone were also studied.

The conclusions drawn from the results of these experiments are discussed in the following pages.

#### a) THE ACTION OF VITAMIN D ON THE MOBILIZATION OF SKELETAL CALCIUM

As mentioned earlier, several experiments have suggested that there is a relationship between the presence or absence of vitamin D and skeletal calcium turnover. Jones (1930, 1933) in serum calcium determinations on dogs maintained under varying dietary conditions, treated with irradiated ergosterol observed increased serum calcium levels and concluded that the source of the excess serum calcium was the food and not the skeleton. On the other hand, "decalcification" of long bones by large doses of vitamin D was demonstrated by histological techniques (Gyorgy 1930) and it was reported that although therapeutic doses of vitamin D promote calcification of bone, large doses cause bone resorption (Shelling 1932 b). Other experiments on rats, led to the conclusion that vitamin D is apparently not essential for mobilization and transfer of bone calcium to rachitic areas of the skeleton (Jones and Cohn 1936). On the other hand it has also been reported that vitamin D, directly or indirectly may influence the calcification of bone (Nicolaysen and Jansen 1939). These and many other studies indicate that vitamin D probably influences the turnover of skeletal calcium, an effect which, however, has been considered as indirect. In contrast, however, studies of normal and rachitic osteogenetic tissue *in vitro* have shown a clearcut action of vitamin D on calcification (Shipley 1924, Howland 1923, Fischmann 1937). Later it was found that young rat calvaria implanted with crystals of vitamin D into the brains of adult animals underwent pronounced local bone resorption (Barnicott 1951), suggesting a direct effect of large doses of vitamin D on bone calcium metabolism. Evidence for a direct effect of physiological doses of vitamin D on bone resorption was provided by the work of Carlsson and co-workers (1952, 1954, 1955). These observations were confirmed by others (Nicolaysen and Eeg-Larsen 1955). Migicovsky, however, (1957) suggested that vitamin D affects the accretion rate of the bone primarily resulting in a secondary effect on bone resorption. San-

karan (1969) repeated Carlsson's experiment and in addition applied balance and kinetic studies in young rats maintained on a low calcium diet. He observed that the low serum calcium values returned to normal with the addition of vitamin D to the diet. This together with an increase in urinary calcium output and a reduced bone ash content was considered to indicate that vitamin D affected bone resorption. However, it was noted by the author that the experiments were inconclusive as to whether vitamin D had a direct or indirect effect on bone calcium mobilization.

Clinical as well as experimental observations have established that an interaction between vitamin D and parathyroid hormone exists. The observations of Crawford et al. (1957) and Harrison et al. (1958) that the action of parathyroid hormone on mineral mobilization from bone requires the presence of vitamin D, have been confirmed by others (Raoul and Marnay 1960, Rasmussen et al. 1963), thus casting doubt on the suggested direct action of vitamin D on bone metabolism. It has been stated that the effect of vitamin D on bone resorption may be that of permitting the circulating parathyroid hormone to exert its characteristic effect (Rasmussen and DeLuca 1963) and that the action of physiological doses of vitamin D on the skeleton, demonstrated by Carlsson and Lindquist (1955) may not be direct, but mediated through the parathyroid glands (Harrison 1964).

With these facts in mind, the effects of vitamin D in the absence of parathyroid hormone were investigated particularly since this relation had received little attention earlier (Hess et al. 1928/29, Greenwald and Gross 1929, Schelling 1932 b, Asher and Jones 1933) and the results were controversial. Thus, the results of the first investigation showed that vitamin D in either normal or high levels failed to restore the serum calcium levels of the thyro-parathyroidectomized rats maintained on a diet with normal Ca to P ratio. This observation was considered to support the view that vitamin D has no direct action on bone calcium mobilization, its characteristic hypercalcaemic effect taking place through other pathways, probably the parathyroids (Sevastikoglou and Ray 1970 a).

Since vitamin D involves various physiological target organs in the body, among others the intestine, the parathyroids, the kidneys and possibly bone, it was felt that it would be impossible to determine whether vitamin D has a direct action on bone by *in vivo* experiments, thus the use of *in vitro* experiments were carried out. The studies of Fischmann (1937) regarding calcification of osteogenetic tissue *in vitro* in a medium derived from normal and vitamin D deficient fowl and those

of Goldhaber (1963), Nichols et al. (1963) and Au and Bartter (1966) involving rat or mice bone maintained *in vitro* led to the conclusion that vitamin D has a direct effect on mobilization of bone calcium. However, possible interactions could not be excluded in these experiments because either the media came from natural sources in other words, were not defined or the bone explants were from animals pretreated with vitamin D. It has been showed that minute amounts of parathyroid hormone in a culture medium can result in bone resorption (Gaillard 1965) and also that minute amounts of vitamin D are required for mobilization of bone mineral in response to parathyroid hormone (Rasmussen and DeLuca 1963). It has been reported, on the other hand, that vitamin D fails to stimulate the resorption of bone maintained *in vitro* in a medium containing serum (Raisz 1965).

These observations made it necessary to study the effect of vitamin D on the calcium mobilization *in vitro* system in the absence of parathyroid hormone. The results indicated that *vitamin D had no direct effect either on the uptake nor on the mobilization of calcium from bone derived from vitamin D deficient and normal young rats* (Sevastikoglou and Ray 1970 d).

The results of both experiments indicate that *the action of vitamin D in large or in physiological doses on mobilization of skeletal calcium is dependent on the presence of parathyroid hormone or some related factor.*

#### b) INTERACTION BETWEEN VITAMIN D AND PARATHYROID HORMONE AND THEIR SIGNIFICANCE FOR THE SURVIVAL OF THE RAT

As mentioned already the results of two of the present experiments led to the conclusion that vitamin D does not have a direct effect on skeletal calcium turnover, (Sevastikoglou and Ray 1970 a and 1970 d). The action of vitamin D has been related to several physiological functions in the body and an interaction between the vitamin and the parathyroids is well documented, although the reported results have not been consistent. Jones (1930) by changing the dietary conditions of parathyroidectomized dogs concluded on the basis of the blood calcium levels that in all probability the antirachitic factor does not act by simply stimulating the parathyroid glands to greater activity. Other experiments indicated that the failure of rachitic animals to respond to parathyroid extract was not directly due to lack of vitamin D (Jones 1935). Blood calcium determinations in vitamin D deficient domestic fowls before and after administration of parathyroid hormone indicated that vitamin D was not necessary

for the action of parathyroid hormone (Hertelendy and Taylor 1960). The same conclusion was drawn from experiments on rats (Toverud 1964) mice (Nichols et al. 1963) and dogs (Ney et al. 1965). On the other hand, experiments on parathyroidectomized and intact rats, under different dietary conditions seemed to indicate that vitamin D and parathyroid hormone had a "synergistic" action on bone metabolism (Crawford et al. 1957). It has been stated that the specific action of parathyroid hormone resulting in mobilization of bone calcium is dependent on the presence of vitamin D or some prior action of it on the target cell (Harrison 1958, Marnay and Raoul 1959, Rasmussen et al. 1963). Harrison and Harrison in 1960 suggested that vitamin D action and the parathyroid hormone effect are probably mutually dependent. Experimental evidence recently provided supported the view that the relation between vitamin D and parathyroid hormone might be based on availability of calcium and not on any direct participation of vitamin D as a co-factor for parathyroid hormone action (Au and Raisz 1967).

Because of the relative confusion and conflicting reports concerning the action of parathyroid hormone on mobilization of bone calcium in the absence of vitamin D a new experiment was carried out. The results showed that young rats maintained for 4 weeks on a high calcium, low phosphorus, vitamin D deficient diet responded with a significant increase in the serum calcium level when given moderate doses (100 IU) of parathyroid extract for 4 consecutive days (Sevastikoglou and Ray 1970 c). This observation led to the conclusion that *while normal levels of parathyroid hormone do not affect the serum calcium level of the vitamin D deficient rat, excess of the hormone results in a rise in serum calcium values, thus suggesting that the hypercalcemic effect of parathyroid hormone in large doses is independent of vitamin D.* The results of this experiment were thus in agreement with those of Toverud (1964), Nichols et al (1963) and Ney et al. (1965) but disagreed to the results reported by Harrison et al (1958), Raoul and Marnay (1960) and Rasmussen et al. (1963). The divergence in results was attributed to differences in the composition of the diets rather than to the degree of vitamin D deficiency, as stated previously (Rasmussen et al. 1963).

In spite of divergences concerning the interrelation between parathyroid hormone and vitamin D, it is generally agreed that these substances are primarily responsible for the calcium homeostasis of the body. It seems further that long term absence of one can be compensated by the other and satisfactory calcium homeostasis effected, the mechanism for this is, however, not known. In the context of the preceding experiments the

TABLE II. Chemical composition of acetone dried powder from diaphyseal cortical bone from young vitamin D deficient and control rats.

	Rats on vitamin D deficient diet (1—6 weeks).	Rats on diet supplemented with vit. D (1—6 weeks).
<i>Hydroxyproline</i>		
a) $\mu\text{g}/\text{mg}$ acetone dried bone powder	Increased values after the 3rd week on diet, consistently lower than in control rats.	Increased values during the time of observation.
b) $\mu\text{g}/\text{mg}$ organic dry weight	Increased values after the 3rd week of observation, lower than in controls.	Irregular slope of the values with a tendency to increase during the time of observation.
<i>Total hexosamine</i>		
a) $\mu\text{g}/\text{mg}$ acetone dried bone powder	Slightly decrease in the slope for mean values after the 2nd week. Consistently higher values than in control rats.	Clearly decrease in the slope for mean values during the period of observation.
b) $\mu\text{g}/\text{mg}$ organic dry weight	Same as above, with less pronounced differences from the corresponding values for the control rats.	Same as above.
<i>Glycosaminoglycans-hexosamine</i>		
a) $\mu\text{g}/\text{mg}$ acetone dried bone powder	Values at almost constant or somewhat increasing levels after the 3rd week on diet. Consistently higher values than for the control rats.	Clearly decrease in the slope for mean values during the period of observation.
b) $\mu\text{g}/\text{mg}$ organic dry weight	Same as above	Same as above
<i>Solubility properties of glycosaminoglycans</i>	Identical to those of the bone for the control rats.	
( calcium Percentage of the total dry weight	Values at constant level during the period of observation. Usually no differences from the corresponding values for the control rats.	Some variations of the values with no slope tendency.

question arose as to whether rats can maintain calcium homeostasis if simultaneously deprived of both vitamin D and parathyroid hormone. Another experiment was undertaken to resolve this question and the results revealed that 4 to 6-week old thyro-parathyroidectomized rats deprived of vitamin D did not survive more than 8 weeks, regardless of whether the calcium intake was adequate or not. If either the parathyroids or vitamin D were present the rats were able to survive even when the calcium intake was very low (Sevastikoglou and Ray 1970 b). From this study it was concluded that in the absence of both parathyroid hormone and vitamin D the body is unable to regulate calcium homeostasis either by mobilizing the skeletal calcium reserves or by intestinal absorption of dietary calcium. Prolonged severe hypocalcaemia, (Sevastikoglou and Ray 1970 c), was probably the cause of the death of the rats.

#### c) EFFECT OF VITAMIN D DEFICIENCY ON THE CHEMISTRY OF THE DIAPHYSEAL CORTICAL BONE OF THE GROWING RAT

Despite numerous studies of the inorganic component of the skeleton in vitamin D deficiency and some studies of the organic fraction as well, (Dikshit 1959, Cipera et al. 1960, Hjertquist 1964) there are no reports on the chemical composition of cortical bone, especially its organic fraction in rickets. An investigation was, therefore, carried out with this special objective (Hjertquist et al. 1970) the results of which are summarized in Table II

These results led to the conclusion that in rats on high calcium, low phosphorus diet vitamin D deficiency does not appreciably affect the inorganic component of the preformed cortical diaphyseal bone, but there are profound changes in its organic component including decreased hydroxyproline and increased glycosaminoglycans — principally chondroitin sulphate — contents. The molecular weight of this polysaccharide underwent no change. The conclusion has been drawn that the state of calcification of the preformed cortical diaphyseal bone was not influenced by vitamin D deficiency in young rats, or in other words that preformed cortical bone does not reflect the characteristic changes of rickets, since the condition is primarily a disturbance of the rapidly growing metaphyseal bone. This observation is however valid for the species used and the span of time of this experiment.

## I. Introduction

Whether and to what extent union of a fracture is taking place is reflected in the stability of the fracture. To determine whether this has increased over a given period is, however, by no means a simple matter, especially in the case of delayed union, but it would seem that an objective measure of the stability is provided by the degree to which the fracture is deflected under a load. To devise a method for following the development of stability by measuring this deflection at intervals was the object of the investigation reported in this monograph.

In principle, the deflection of the fractured bone is recorded as a function of the applied bending force, and an instrument has been designed by means of which such a registration can be made. The reliability of the instrument has been determined experimentally on autopsy specimens of the tibia, and the suitability of the method for clinical use has been examined by performing measurements on patients.

The deflection of a bone produced by the application of a load is dependent on its modulus of elasticity. This quantity, which affords a basis for comparison of the stiffness of bones, can be calculated from the deflection of the bone and the moment of inertia of its cross section. As no picture of the section can be obtained in the living subject a formula has been derived that provides an approximate value of the moment of inertia of this area. The required dimensions of the cross section are determined from radiographs taken with known projections.

Thus, from the deflection of the bone and the moment of inertia a rough measure of the stability of the fracture can be obtained. The total deflection of the bone is composed of the deflection of the bone fragments and that within the actual fracture. The former component is obtained from measurements on the other, sound, tibia, and by subtracting this from the total deflection, the deflection within the actual fracture is obtained, and hence the flexural rigidity of the fracture callus can be determined. This rigidity reflects the stage of healing and hence indicates when the various steps of treatment should be introduced—for example, when it is safe to permit normal functional loading of the leg.

from calculated directions of the principal central axes. From photographic enlargements of the cross section of a bone Mather (1967) calculated its moment of inertia by a graphical method devised by Mohr (Andrews, 1934). Knese *et al.* (1956) determined the moment of inertia and the directions of the principal central axes of bone specimens by means of an integrator, as did Comtet *et al.* (1967).

The elasticity and strength of bone vary according to the type of deforming force and also according to the relative position of the longitudinal axis of the test specimen and axis of the bone. The elasticity and strength are least in the transverse direction and greatest parallel to the axis (Olivo *et al.*, 1937; Dempster & Liddicoat, 1952; Dempster & Coleman, 1961; Sedlin, 1965; Sedlin & Hirsch, 1966; Hirsch & da Silva, 1967; Blaimont, 1968; Lang, 1969). This is due to the largely axial orientation of the collagen fibres; these have a high tensile strength and modulus of elasticity for axial tension. Apatite, whose crystals are oriented with their longitudinal axes parallel to the collagen fibrils, has a low tensile but high compressive strength, and a higher modulus of elasticity for axial compression (Glimcher, 1959; Molnar, 1960; Currey, 1964; Sweeney *et al.*, 1965).

According to three current theories on the combined function of the collagen and the apatite these components can act as a compound bar, the collagen fibres can be pre-stressed so that the bone behaves as a pre-stressed material (Knese, 1958), or the bone can constitute a two-phase material similar to fibre glass (Currey, 1964; Mack, 1964).

The modulus of elasticity is slightly higher for tension than compression. When a bone is bent the stress and strain are compressive on the concave side and tensile on the convex, and the modulus of elasticity in bending will be a resultant of the values for compression and tension. There is a close relationship between the maximum bending strength and the modulus of elasticity in bending, which is the parameter that can be used in clinical work for comparing different vital bones (Weir *et al.*, 1949; Smith & Walmsley, 1959; Sedlin & Hirsch, 1966; Mather, 1967).

Values of the modulus of elasticity in bending that have been reported for the human tibia include  $(0.81-1.42) \times 10^3$  (Smith & Walmsley, 1959),  $1.22 \times 10^3$  (Moroshima, 1960),  $(1.4-2.6) \times 10^3$  (Rabischong, 1965), and  $1.44 \times 10^3$  kgf/mm<sup>2</sup> (Mather, 1967); and for the femur,  $(1.06-1.97) \times 10^3$  (Sedlin & Hirsch, 1966), and  $1.36 \times 10^3$  kgf/mm<sup>2</sup> (Mather, 1967).

## II. *Physical properties of bone*

Since Wertheim's studies published in 1847 the physical properties of bone have been a subject of increasing interest, and many of them have been elucidated in reviews published in recent years (Evans 1957, 1966; Knese 1958; Blaimont 1968).

Bone being a heterogeneous anisotropic substance with varying structure, the determination of its deformation and moment of inertia presents considerable difficulty; but neither of these properties need be known for the ultimate strength to be found. In tension and compression the stress is distributed uniformly over the cross sectional area and if tensile and compressive tests can be used to obtain values for the required mechanical properties of the bone, a knowledge of the moment of inertia is unnecessary; but if bending or torsional tests are used, this moment must be known, because, like the modulus of elasticity or rigidity, it is a critical quantity for the magnitude of the deflection or torsion.

If test specimens can be used instead of large pieces or intact bones, the moment of inertia can be accurately calculated from the cross section. Most studies of the mechanical properties of bone have been performed on such test specimens (Olivo *et al.*, 1937; Carothers *et al.*, 1949; Dempster & Liddicoat, 1952; Evans, 1957; Dempster & Coleman, 1961; Vose, 1962; McElhaney, 1964; Sedlin, 1965; Sweeney *et al.*, 1965; Sedlin & Hirsch, 1966; Lindahl & Lindgren, 1967). Where large pieces of bone or intact bones have been used, it has been values for the properties in tension or compression or for the ultimate strength that have been determined; otherwise the moment of inertia of the section must have been calculated.

In determinations of the moment of inertia the cross section of the bone has been taken as circular or elliptical (Grunewald, 1920; Bell *et al.*, 1941; Weir *et al.*, 1949; Vose & Kubala, 1961; Currey, 1969). A numerical integration of the moment (see page 33) after balancing the centre of gravity has been performed and the principal central axes have been inserted by inspection (Koch, 1917). Blaimont (1968) has determined the moment of inertia in a like manner after finding the direction of the axes experimentally. By graphic integration Marique (1945) found the moment of inertia

from calculated directions of the principal central axes. From photographic enlargements of the cross section of a bone Mather (1967) calculated its moment of inertia by a graphical method devised by Mohr (Andrews, 1934). Knese *et al.* (1956) determined the moment of inertia and the directions of the principal central axes of bone specimens by means of an integrator, as did Comtet *et al.* (1967).

The elasticity and strength of bone vary according to the type of deforming force and also according to the relative position of the longitudinal axis of the test specimen and axis of the bone. The elasticity and strength are least in the transverse direction and greatest parallel to the axis (Olivo *et al.*, 1937; Dempster & Liddicoat, 1952; Dempster & Coleman, 1961; Sedlin, 1965; Sedlin & Hirsch, 1966; Hirsch & da Silva, 1967; Blaimont, 1968; Lang, 1969). This is due to the largely axial orientation of the collagen fibres; these have a high tensile strength and modulus of elasticity for axial tension. Apatite, whose crystals are oriented with their longitudinal axes parallel to the collagen fibrils, has a low tensile but high compressive strength, and a higher modulus of elasticity for axial compression (Glimcher, 1959; Molnar, 1960; Currey, 1964; Sweeney *et al.*, 1965).

According to three current theories on the combined function of the collagen and the apatite these components can act as a compound bar, the collagen fibres can be pre-stressed so that the bone behaves as a pre-stressed material (Knese, 1958), or the bone can constitute a two-phase material similar to fibre glass (Currey, 1964; Mack, 1964).

The modulus of elasticity is slightly higher for tension than compression. When a bone is bent the stress and strain are compressive on the concave side and tensile on the convex, and the modulus of elasticity in bending will be a resultant of the values for compression and tension. There is a close relationship between the maximum bending strength and the modulus of elasticity in bending, which is the parameter that can be used in clinical work for comparing different vital bones (Weir *et al.*, 1949, Smith & Walmsley, 1959, Sedlin & Hirsch, 1966; Mather, 1967).

Values of the modulus of elasticity in bending that have been reported for the human tibia include  $(0.81-1.42) \times 10^3$  (Smith & Walmsley, 1959),  $1.22 \times 10^3$  (Motoshima, 1960),  $(1.4-2.6) \times 10^3$  (Rabischong, 1965), and  $1.44 \times 10^3$  kgf/mm<sup>2</sup> (Mather, 1967), and for the femur,  $(1.06-1.97) \times 10^3$  (Sedlin & Hirsch, 1966), and  $1.36 \times 10^3$  kgf/mm<sup>2</sup> (Mather, 1967).

## II. *Physical properties of bone*

Since Wertheim's studies published in 1847 the physical properties of bone have been a subject of increasing interest, and many of them have been elucidated in reviews published in recent years (Evans 1957, 1966; Knese 1958; Blaimont 1968).

Bone being a heterogeneous anisotropic substance with varying structure, the determination of its deformation and moment of inertia presents considerable difficulty; but neither of these properties need be known for the ultimate strength to be found. In tension and compression the stress is distributed uniformly over the cross sectional area and if tensile and compressive tests can be used to obtain values for the required mechanical properties of the bone, a knowledge of the moment of inertia is unnecessary; but if bending or torsional tests are used, this moment must be known, because, like the modulus of elasticity or rigidity, it is a critical quantity for the magnitude of the deflection or torsion.

If test specimens can be used instead of large pieces or intact bones, the moment of inertia can be accurately calculated from the cross section. Most studies of the mechanical properties of bone have been performed on such test specimens (Olivo *et al.*, 1937; Carothers *et al.*, 1949; Dempster & Liddicoat, 1952; Evans, 1957; Dempster & Coleman, 1961; Vose, 1962; McElhaney, 1964; Sedlin, 1965; Sweeney *et al.*, 1965; Sedlin & Hirsch, 1966; Lindahl & Lindgren, 1967). Where large pieces of bone or intact bones have been used, it has been values for the properties in tension or compression or for the ultimate strength that have been determined; otherwise the moment of inertia of the section must have been calculated.

In determinations of the moment of inertia the cross section of the bone has been taken as circular or elliptical (Grunewald, 1920; Bell *et al.*, 1941; Weir *et al.*, 1949; Vose & Kubala, 1961; Currey, 1969). A numerical integration of the moment (see page 33) after balancing the centre of gravity has been performed and the principal central axes have been inserted by inspection (Koch, 1917). Blaimont (1968) has determined the moment of inertia in a like manner after finding the direction of the axes experimentally. By graphic integration Marique (1945) found the moment of inertia

and where  $\varphi$  is the required angle between one principal central axis of the tibia section and the axis of  $x$ .  $I_{x^0}$  and  $I_{y^0}$  are the moments of inertia about the axes of a coordinate system having the origin in the centroid but rotated through  $45^\circ$  in relation to the coordinate system  $xy$ .  
The principal moments of inertia of the tibia section are given by the formula:

$$\frac{I_{\max}}{I_{\min}} = \frac{1}{2} \left\{ (I_x + I_y) \pm \left[ (I_x - I_y)^2 + (I_{x^0} - I_{y^0})^2 \right]^{1/2} \right\} \dots [4]$$

If the central axis is rotated through an angle  $\varphi$  about the centroid in the plane of section the moment of inertia will change to:

$$I_\varphi = I_{\min} \cos^2 \varphi + I_{\max} \sin^2 \varphi \dots [5]$$

Its magnitude is thus dependent on the angle  $\varphi$  and the magnitude of  $I_{\min}$  and  $I_{\max}$ .

The maximum deflection of a simple beam freely supported at the ends and loaded at its midpoint is obtained when the force acts against the minimum moment of inertia, that is to say, in the bending plane with respect to the minimum moment of inertia. If the line of action of the bending force  $P$  (Fig. 1) applied to the tibia, regarded as a simple beam,

does not lie in the bending plane  $YZ$  with respect to the minimum moment of inertia, the deflection will occur in the direction of a resultant  $v$ , whose components  $v_x$  and  $v_y$  coincide with the axes  $x$ ,  $y$ , the principal axes of the tibia section.

If the line of action of the force  $P$  makes an angle  $\beta$  with the plane  $YZ$ , one component of the force,  $P \sin \beta$ , acts along the axis of  $x$ , and the other,  $P \cos \beta$ , acts along the axis of  $y$ . The components of the deflection are thus  $v_x = P L^3 \sin \beta / 48 E I_{\max}$ , and  $v_y = P L^3 \cos \beta / 48 E I_{\min}$ . The resultant  $v$ , will act in a bending plane making an angle  $\varphi$  with the bending plane  $YZ$ , where

$$\tan \varphi = I_{\min} \tan \beta / I_{\max} \dots [6]$$

The magnitude of the total deflection  $v$ , can be calculated from  $v_x$  and  $v_y$  by application of the Theorem of Pythagoras. The quantity recorded,

### III. Notation and formulae

The following notation has been adopted in this monograph.

■ Stress	$M$ Bending moment
■ Strain	$P$ Concentrated load
$v$ Deflection recorded under load	$a$ Diameter of marrow space
$\delta$ Corrected deflection	$b$ Breadth of section of the tibia

#### FORMULAE

The derivations of the formulae used in this study are to be found in the usual reference books of mechanics (Andrews, 1934; Baumeister & Marks, 1958). In the following theoretical analysis of the deflection of the tibia it is assumed that bone is an ideal elastic material.

The application of a force to an elastic material produces a stress  $\sigma$  that is proportional to the strain  $\epsilon$  in accordance with Hooke's law:

$$\sigma = E \epsilon \quad \dots \dots \dots [1]$$

where  $E$ , the modulus of elasticity, is a constant that is valid below the limit of proportionality. It can be calculated from the expression for the deflection of a uniform straight beam freely supported at both ends and subjected to a load at its midpoint. The formula, which is based on Mohr's theorem, is

$$\delta = PL^3/48 EI \quad \dots \dots \dots [2]$$

All the values of the modulus of elasticity stated in this report refer to bending.

The positions of the principal central axes are obtained from the equation:

$$\tan 2 \varphi = (I_{135^\circ} - I_{45^\circ}) / (I_y - I_x) \quad \dots \dots \dots [3]$$

where  $I_x$  and  $I_y$  are the moments of inertia of the tibia section about the axes of a rectangular coordinate system  $xy$  with the origin in the centroid,

and where  $\eta$  is the required angle between one principal central axis of the tibia section and the axis of  $x$ .  $I_{x'}$  and  $I_{y'}$  are the moments of inertia about the axes of a coordinate system having the origin in the centroid but rotated through  $45^\circ$  in relation to the coordinate system  $xy$ .

The principal moments of inertia of the tibia section are given by the formula:

$$I_{\max} = \frac{1}{2} \left\{ (I_x + I_y) \pm \left[ (I_x - I_y)^2 + (I_{xy} - I_{x'y'})^2 \right]^{1/2} \right\} \quad [4]$$

If the central axis is rotated through an angle  $\eta$  about the centroid in the plane of section the moment of inertia will change to:

$$I_\eta = I_{\min} \cos^2 \eta + I_{\max} \sin^2 \eta \quad [5]$$

Its magnitude is thus dependent on the angle  $\eta$  and the magnitude of  $I_{\min}$  and  $I_{\max}$ .

The maximum deflection of a simple beam freely supported at the ends and loaded at its midpoint is obtained when the force acts against the minimum moment of inertia, that is to say, in the bending plane with respect to the minimum moment of inertia. If the line of action of the bending force  $P$  (Fig. 1) applied to the tibia, regarded as a simple beam,

FIGURE 1 Projections of the force  $P$  on the principal central axes  $x$  and  $y$ . The axis of the tibia coincides with the axis of  $x$ .  $v_x$  and  $v_y$  are the components of the deflection along the respective axes, and  $v$  is the resultant in the bending plane making an angle  $\eta$  with the plane  $YZ$ , with which the line of action of  $P$  makes an angle  $\beta$ .

does not lie in the bending plane  $YZ$  with respect to the minimum moment of inertia, the deflection will occur in the direction of a resultant  $v$ , whose components  $v_x$  and  $v_y$  coincide with the axes  $x$ ,  $y$ , the principal axes of the tibia section.

If the line of action of the force  $P$  makes an angle  $\beta$  with the plane  $YZ$ , one component of the force,  $P \sin \beta$ , acts along the axis of  $x$ , and the other,  $P \cos \beta$ , acts along the axis of  $y$ . The components of the deflection are thus  $v_x = PL^3 \sin \beta / 48 EI_{\min}$ , and  $v_y = PL^3 \cos \beta / 48 EI_{\max}$ . The resultant  $v$ , will act in a bending plane making an angle  $\eta$  with the bending plane  $YZ$ , where:

$$\tan \eta = I_{\max} \tan \beta / I_{\min} \quad [6]$$

The magnitude of the total deflection  $v$ , can be calculated from  $v_x$  and  $v_y$  by application of the Theorem of Pythagoras. The quantity recorded,

### III. Notation and formulae

The following notation has been adopted in this monograph.

$\sigma$ Stress	$M$ Bending moment
$\epsilon$ Strain	$P$ Concentrated load

$\delta$ Corrected deflection	$b$ Breadth of section of the tibia
$E$ Young's modulus of elasticity	$d$ Thickness of section of the tibia
$I$ Moment of inertia	$l$ Distance from nearer outer pin to fracture
$L$ Length, span	

#### FORMULAE

The derivations of the formulae used in this study are to be found in the usual reference books of mechanics (Andrews, 1934; Baumeister & Marks, 1958). In the following theoretical analysis of the deflection of the tibia it is assumed that bone is an ideal elastic material.

The application of a force to an elastic material produces a stress  $\sigma$  that is proportional to the strain  $\epsilon$  in accordance with Hooke's law:

$$\sigma = E \epsilon \quad \dots \dots \dots [1]$$

where  $E$ , the modulus of elasticity, is a constant that is valid below the limit of proportionality. It can be calculated from the expression for the deflection of a uniform straight beam freely supported at both ends and subjected to a load at its midpoint. The formula, which is based on Mohr's theorem, is

$$\delta = PL^3/48 EI \quad \dots \dots \dots [2]$$

All the values of the modulus of elasticity stated in this report refer to bending.

The positions of the principal central axes are obtained from the equation:

$$\tan 2 \varphi = (I_{135} - I_{45}) / (I_y - I_x) \quad \dots \dots \dots [3]$$

where  $I_x$  and  $I_y$  are the moments of inertia of the tibia section about the axes of a rectangular coordinate system  $xy$  with the origin in the centroid,

and where  $\varphi$  is the required angle between one principal central axis of the tibia section and the axis of  $x$ .  $I_{x^0}$  and  $I_{y^0}$  are the moments of inertia about the axes of a coordinate system having the origin in the centroid but rotated through  $45^\circ$  in relation to the coordinate system  $xy$ .  
The principal moments of inertia of the tibia section are given by the formula:

$$I_{\max} = \frac{1}{2} \left\{ (I_x + I_y) \pm \left[ (I_x - I_y)^2 + (I_{xy^0} - I_{xy})^2 \right]^{1/2} \right\} \quad [4]$$

If the central axis is rotated through an angle  $\varphi$  about the centroid in the plane of section the moment of inertia will change to:

$$I_\varphi = I_{\min} \cos^2 \varphi + I_{\max} \sin^2 \varphi \quad [5]$$

Its magnitude is thus dependent on the angle  $\varphi$  and the magnitude of  $I_{\min}$  and  $I_{\max}$ .

The maximum deflection of a simple beam freely supported at the ends and loaded at its midpoint is obtained when the force acts against the minimum moment of inertia, that is to say, in the bending plane with respect to the minimum moment of inertia. If the line of action of the bending force  $P$  (Fig. 1) applied to the tibia, regarded as a simple beam,

FIGURE 1 Projections of the force  $P$  on the principal central axes  $x$  and  $y$ . The axis of the tibia coincides with the axis of  $x$ .  $v_x$  and  $v_y$  are the components of the deflection along the respective axes, and  $v$  is the resultant in the bending plane making an angle  $\beta$  with the plane  $YZ$ , with which the line of action of  $P$  makes an angle  $\beta$ .

does not lie in the bending plane  $YZ$  with respect to the minimum moment of inertia, the deflection will occur in the direction of a resultant  $v$ , whose components  $v_x$  and  $v_y$  coincide with the axes  $x$ ,  $y$ , the principal axes of the tibia section.

If the line of action of the force  $P$  makes an angle  $\beta$  with the plane  $YZ$ , one component of the force,  $P \sin \beta$ , acts along the axis of  $x$ , and the other,  $P \cos \beta$ , acts along the axis of  $y$ . The components of the deflection are thus  $v_x = PL^3 \sin \beta / 48 EI_{\max}$ , and  $v_y = PL^3 \cos \beta / 48 EI_{\min}$ . The resultant  $v$ , will act in a bending plane making an angle  $\varphi$  with the bending plane  $YZ$ , where:

$$\tan \varphi = I_{\min} \tan \beta / I_{\max} \quad [6]$$

The magnitude of the total deflection  $v$ , can be calculated from  $v_x$  and  $v_y$  by application of the Theorem of Pythagoras. The quantity recorded,

#### FORMULAE

The derivations of the formulae used in this study are to be found in the usual reference books of mechanics (Andrews, 1934; Baumeister & Marks, 1958). In the following theoretical analysis of the deflection of the tibia it is assumed that bone is an ideal elastic material.

The application of a force to an elastic material produces a stress  $\sigma$  that is proportional to the strain  $\epsilon$  in accordance with Hooke's law:

$$\sigma = E \epsilon \quad \dots \dots \dots [1]$$

where  $E$ , the modulus of elasticity, is a constant that is valid below the limit of proportionality. It can be calculated from the expression for the deflection of a uniform straight beam freely supported at both ends and subjected to a load at its midpoint. The formula, which is based on Mohr's theorem, is

$$\delta = PL^3/48 EI \quad \dots \dots \dots [2]$$

All the values of the modulus of elasticity stated in this report refer to bending.

The positions of the principal central axes are obtained from the equation:

$$\tan 2 \varphi = (I_{135^\circ} - I_{45^\circ}) / (I_y - I_x) \quad \dots \dots \dots [3]$$

where  $I_x$  and  $I_y$  are the moments of inertia of the tibia section about the axes of a rectangular coordinate system  $xy$  with the origin in the centroid,

and where  $\varphi$  is the required angle between one principal central axis of the tibia section and the axis of  $x$ .  $I_{xz}^0$  and  $I_{yz}^0$  are the moments of inertia about the axes of a coordinate system having the origin in the centroid but rotated through  $45^\circ$  in relation to the coordinate system  $xy$ .

The principal moments of inertia of the tibia section are given by the formula:

$$I_{max/min} = \frac{1}{2} \left\{ (I_x + I_y) \pm \left[ (I_x - I_y)^2 + (I_{xz}^0 - I_{yz}^0)^2 \right]^{1/2} \right\} \dots [4]$$

If the central axis is rotated through an angle  $\varphi$  about the centroid in the plane of section the moment of inertia will change to:

$$I_\varphi = I_{min} \cos^2 \varphi + I_{max} \sin^2 \varphi \dots \dots \dots [5]$$

Its magnitude is thus dependent on the angle  $\varphi$  and the magnitude of  $I_{min}$  and  $I_{max}$ .

The maximum deflection of a simple beam freely supported at the ends and loaded at its midpoint is obtained when the force acts against the minimum moment of inertia, that is to say, in the bending plane with respect to the minimum moment of inertia. If the line of action of the bending force  $P$  (Fig. 1) applied to the tibia, regarded as a simple beam,

FIGURE 1 Projections of the force  $P$  on the principal central axes  $x$  and  $y$ . The axis of the tibia coincides with the axis of  $z$ .  $v_x$  and  $v_y$  are the components of the deflection along the respective axes, and  $v$  is the resultant in the bending plane making an angle  $\varphi$  with the plane  $YZ$ , with which the line of action of  $P$  makes an angle  $\beta$ .

does not lie in the bending plane  $YZ$  with respect to the minimum moment of inertia, the deflection will occur in the direction of a resultant  $v$ , whose components  $v_x$  and  $v_y$  coincide with the axes  $x$ ,  $y$ , the principal axes of the tibia section.

If the line of action of the force  $P$  makes an angle  $\beta$  with the plane  $YZ$ , one component of the force,  $P \sin \beta$ , acts along the axis of  $x$ , and the other,  $P \cos \beta$ , acts along the axis of  $y$ . The components of the deflection are thus  $v_x = PL^3 \sin \beta / 48 EI_{max}$ , and  $v_y = PL^3 \cos \beta / 48 EI_{min}$ . The resultant  $v$ , will act in a bending plane making an angle  $\varphi$  with the bending plane  $YZ$ , where:

$$\tan \varphi = I_{min} \tan \beta / I_{max} \dots \dots \dots [6]$$

The magnitude of the total deflection  $v$ , can be calculated from  $v_x$  and  $v_y$  by application of the Theorem of Pythagoras. The quantity recorded,

minimum moment of inertia of the cross sections of 5 tibias are shown at the top of figure 4. For one of the bones the moment was determined by means of integrator, and for the other by numerical integration. The minimum moment of inertia of the tibia  $I_{min}$  and that of each section  $I_{min}(x)$  is placed on the axis of ordinates and is plotted as a function of the length of the tibia. Thus, the curve for each bone shows the variation of  $I_{min}$  along the tibia. From the values in each curve the deflection curve for each specimen was calculated by means of a computer. At the bottom of figure 4 one such curve—for specimen 2, left tibia—is compared with that which would be obtained if the tibia were a straight uniform beam. At the same time as the curves were computed the value of the constant in eqn. [2] was obtained for each of the five bones and the two loading systems with the supporting pins 21 and 24 cm apart (see page 19). As regards the minimum moment of inertia for the smallest cross section, the constant in the formula for the deflection of the tibia will be  $1/66$  and  $1/67$ , respectively. The standard deviation of the constants for the five bones is 5 per cent. The expressions for the deflection of the tibia are thus:

$$\delta_{21} = 21^3 P / 66 E I_{min} \quad \delta_{24} = 24^3 P / 67 E I_{min} \quad \dots \quad [9]$$

The original eqn. [2] was used in the subsequent calculations for determining  $E$ , and the values of the modulus of elasticity so obtained are designated the apparent modulus of elasticity, " $E$ ", while the values yielded by eqn. [9] are given below together with the magnitude of the constant.

### DEFLECTION OF THE CALLUS

Fracture callus may be regarded as a visco-elastic material. During the course of the union the viscous component diminishes and the elasticity of the callus increases until it is ultimately the same as for the rest of the bone. This may be checked by measuring the distance between the rising and descending part of the load-deflection curve when the applied force is zero.

A true model for the deflection of the callus would thus require the application of advanced plastic theory, in which the viscous and elastic component are functions of the time. Account would also need to be taken

FIGURE 3 Cross sections taken from 14 cm proximally (+) to 16 cm distally (—) of the midpoint (0) of a tibia specimen. The intersecting lines are the principal central axes of the moment of inertia, whose positions were determined by means of an integrator. A single line through the section marks the direction of the principal central axis of the minimum moment of inertia, which was inserted by inspection.

as a spring joint, a joint which can take up a bending moment, and later as a very short beam, where the viscous component and shear are neglected. This approach is necessary in order to obtain a conception of the physical properties of the callus.

In the model, the fractured bone is regarded as two beams connected by a spring joint; the applied bending moment of the spring joint is given by the expression  $M = C\alpha$ , where  $C$  is the spring constant and  $\alpha$  the angulation of the spring joint. The total deflection of the model  $\delta_{tot}$  is the sum of the deflections of the beams  $\delta_l$  and the spring joint  $\delta_j$ , that is,

$$\delta_{tot} = \delta_l + \delta_j$$

The angle  $\alpha$  can be obtained in terms of  $\delta_l$  and  $l$  as follows (Fig. 5).

FIGURE 5 A fractured tibia represented as a beam  $AC$  on two end supports distance  $L$  apart, with a concentrated load  $P$ .  $B$  indicates the fracture at distance  $l$  from nearer end support  $\delta_l$  is the displacement at the mid-point of  $AC$ ,  $\alpha$  is the angle of deflection at the callus, and  $\delta_{max}$  the maximum displacement,  $P/2$  is the reaction at the end supports

From the theorem relating to the external angle,  $\alpha = \beta + \gamma$ . Since for small angles the tangent is nearly equal to the angle itself,  $\beta = \delta_l / (L/2)$  and  $\gamma = \delta_{max} / l$ . But, from the theorem on similar triangles,  $\delta_l / (L/2) = \delta_{max} / (L-l)$ ; thus  $\delta_{max} = 2\delta_l (L-l) / L$ . Hence,  $\gamma = 2\delta_l (L-l) / Ll$ . Inserting these values of  $\beta$  and  $\gamma$  in the equation  $\alpha = \beta + \gamma$ , we have

$$\alpha = 2\delta_l / L + 2\delta_l (L-l) / Ll = 2\delta_l / l$$

But the bending moment acting on the spring joint  $M = Pl/2$ . Therefore, [10]

$$C = Pl^2 / 4\delta_l$$

where  $C$  is the stiffness of the callus in the model for the fractured bone. In the course of healing  $C$  increases inversely as the deflection of the callus  $\delta_l$ . The equation is valid when the load-deflection curves of the fractured bones are linear, as they were in most cases at the stage of clinical stability. It is of interest to see how the stiffness develops in the callus independent of the dimensions of very short length  $s$ .

$C = M/\alpha$ , but for a beam  $\alpha = Ms/EI/l$ , and hence  $C = EI/l^3$ . But since

$$C = Pl^2 / 4\delta_l \text{ and thus we have:}$$

$$s/EI = 4\delta_l l^3 / Pl^2$$

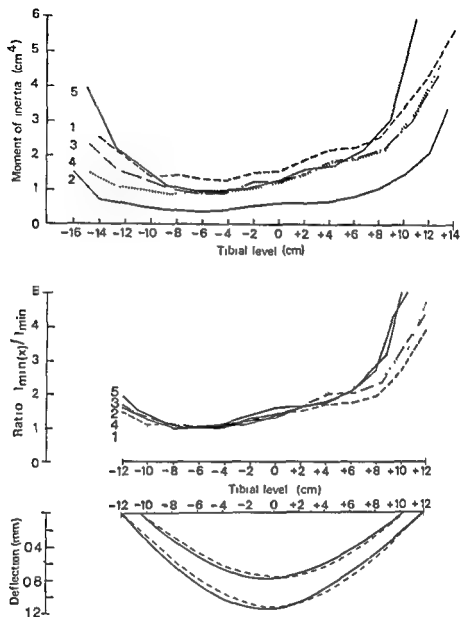

FIGURE 4 *Top*—Variation of the minimum moment of inertia of the sections along the tibia. Specimens 1—5.  
*Middle*—Variation of the ratio  $I_{min(x)}/I_{min}$  along the tibia for the same specimens

of the shear accompanying bending. As such a model could not be applied in practice and would be understood only by specialists in the mechanics of materials, a simple model was chosen where the callus is first regarded

as a spring joint, a joint which can take up a bending moment, and later as a very short beam, where the viscous component and shear are neglected. This approach is necessary in order to obtain a conception of the physical properties of the callus.

In the model, the fractured bone is regarded as two beams connected by a spring joint; the applied bending moment of the spring joint is given by the expression  $M = C\alpha$ , where  $C$  is the spring constant and  $\alpha$  the angulation of the spring joint. The total deflection of the model  $\delta_{tot}$  is the sum of the deflections of the beams  $\delta_1$  and the spring joint  $\delta_2$ , that is,

$$\delta_{tot} = \delta_1 + \delta_2$$

The angle  $\alpha$  can be obtained in terms of  $\delta_1$  and  $l$  as follows (Fig. 5).

FIGURE 5 A fractured bone represented as a beam AC on two end supports distance  $L$  apart, with a concentrated load  $P$  indicating the fracture at distance  $l$  from nearer end support  $\delta_1$  is the displacement at the mid-point of AC,  $\alpha$  is the angle of deflection at the callus, or  $\delta_{max}$  the maximum displacement;  $P/2$  is the reaction at the end supports

From the theorem relating to the external angle,  $\alpha = \beta + \gamma$ . Since for small angles the tangent is nearly equal to the angle itself,  $\beta = \delta_{max} / (L/2)$  and  $\gamma = \delta_{max} / l$ . But, from the theorem on similar triangles,  $\delta_1 / (L-l) = \delta_{max} / (L-l)$ ; thus  $\delta_{max} = 2\delta_1 (L-l) / L$ . Hence,  $\gamma = 2\delta_1 (L-l) / Ll$ . Inserting these values of  $\beta$  and  $\gamma$  in the equation  $\alpha = \beta + \gamma$ , we have

$$\alpha = 2\delta_1 / L + 2\delta_1 (L-l) / Ll = 2\delta_1 / l$$

But the bending moment acting on the spring joint  $M = Pl/2$ . Therefore,

$$C = Pl / 4\delta_1$$

where  $C$  is the stiffness of the callus in the model for the fractured bone. In the course of healing  $C$  increases inversely as the deflection of the callus  $\delta_1$ . The equation is valid when the load-deflection curves of the fractured bones are linear, as they were in most cases at the stage of clinical stability.

It is of interest to see how the stiffness develops in the callus independent of the dimensions of the callus. In the model the spring joint is substituted by a beam of very short length  $s$ .

$C = M / \alpha$ , but for a beam  $\alpha = Ms / EI$ , and hence  $C = EI / s$ . But since  $C = Pl / 4\delta_1$  and thus we have:

$$s / EI = 4 \delta_1 / Pl$$

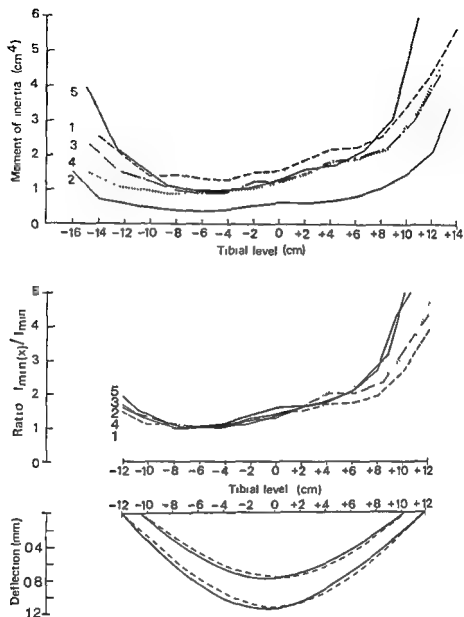

FIGURE 4 *Top*—Variation of the minimum moment of inertia of the sections along the tibia. Specimens 1—5.  
*Middle*.—Variation of the ratio  $I_{min(x)}/I_{min}$  along the tibia for the same specimens

*Bottom*.—Deflection of specimen 2 (continuous line) and of an ideal beam loaded by a force of 5 kgf, with the end supports 24 and 21 cm apart (broken line)

of the shear accompanying bending. As such a model could not be applied in practice and would be understood only by specialists in the mechanics of materials, a simple model was chosen where the callus is first regarded

as a spring joint, a joint which can take up a bending moment, and later a very short beam, where the viscous component and shear are neglected. This approach is necessary in order to obtain a conception of the physical properties of the callus.

In the model, the fractured bone is regarded as two beams connected by a spring joint; the applied bending moment of the spring joint is given by the expression  $M = Ca$ , where  $C$  is the spring constant and  $a$  the angulation of the spring joint. The total deflection of the model  $\delta_{tot}$  is the sum of the deflections of the beams  $\delta_1$  and the spring joint  $\delta_s$ , that is,

$$\delta_{tot} = \delta_1 + \delta_s$$

The angle  $\alpha$  can be obtained in terms of  $\delta_1$  and  $l$  as follows (Fig. 5).

FIGURE 5 A fractured tibia represented as a beam AC on two end supports distance  $L$  apart, with a concentrated load  $P$ .  $B$  indicates the fracture at distance  $l$  from nearer end support.  $\delta_1$  is the displacement at the mid-point of AC,  $\alpha$  is the angle of deflection at the end support, and  $\delta_{max}$  the maximum displacement;  $P/2$  is the reaction at the end supports.

From the theorem relating to the external angle,  $\alpha = \beta + \gamma$ . Since for small angles the tangent is nearly equal to the angle itself,  $\beta = \delta_1/(L/2)$  and  $\gamma = \delta_{max}/l$ . But, from the theorem on similar triangles,  $\delta_1/(L/2) = \delta_{max}/(L-l)$ ; thus  $\delta_{max} = 2\delta_1(L-l)/L$ . Hence,  $\gamma = 2\delta_1(L-l)/Ll$ . Inserting these values of  $\beta$  and  $\gamma$  in the equation  $\alpha = \beta + \gamma$ , we have

$$\alpha = 2\delta_1/L + 2\delta_1(L-l)/Ll \\ = 2\delta_1/l$$

But the bending moment acting on the spring joint  $M = Pl/2$ . Therefore,

$$C = pl^2/4\delta_1 \quad [10]$$

where  $C$  is the stiffness of the callus in the model for the fractured bone. In the course of healing  $C$  increases inversely as the deflection of the callus  $\delta_1$ . The equation is valid when the load-deflection curves of the fractured bones are linear, as they were in most cases at the stage of clinical stability. It is of interest to see how the stiffness develops in the callus independent of the dimensions of the callus. In the model the spring joint is substituted by a beam of very short length  $s$ .

$C = M/a$ , but for a beam  $a = Ms/EI/s$ , and hence  $C = EI/s$ . But since  $C = pl^2/4\delta_1$ , and thus we have:

$$s/EI = 4\delta_1 l^2/pl^2 \quad [11]$$

If the three beams are taken to represent the fractured tibia,  $E_f$ , in eqn. [11], is the modulus of elasticity,  $I_f$  the moment of inertia and  $\delta_f$  the deflection of the callus, which has a very short length of  $s$ .

$\delta_f$  is calculated in the following way. The bone fragments corresponding to the two beams have an observed deflection that is regarded as being equal to the observed deflection of the sound tibia,  $v_t$ . By subtracting  $v_t$  from the observed deflection of the fractured tibia,  $v_{tot}$ , the deflection of the callus is obtained. Thus,

$$\delta_f = v_{tot} - v_t \quad \dots \quad [12]$$

The ratio  $s/E_f$  is a measure of the stability of the callus. Neither  $s$  nor  $I_f$  can be determined. Since the former moment of inertia of the bone should be recovered on healing, the moment of inertia of the callus,  $I_f$ , was considered to be equal to that of the sound tibia at the level corresponding to that of the fracture. It is obtained as a multiple of  $I_{min}$  from the curves for the ratio  $I_{min(x)}/I_{min}$  (Fig. 4, middle).

When a fracture heals the deflection of the callus decreases and  $\delta_f$  approaches zero; thus  $E_f$  approaches very high values.

## STATISTICAL METHODS

In the evaluation of the results the usual statistical methods were applied and the procedures are to be found in *Statistical Methods* by G. W. Snedecor and W. G. Cochran (1967).

The results of the measurements on the right and left tibias or of different methods of measurements were compared by analysis of variance, and the probabilities,  $P$ , of hypotheses set up were determined by means of the  $F$  ratio. Student's  $t$  was used to determine confidence intervals for the observed means.

Linear regression analyses were performed by the method of least squares.

## IV. Methods

### MEASURING INSTRUMENT

The instrument consists of an aluminium beam (4 in Fig. 6), referred to as the "measuring beam", three stainless steel pins (1, 2 and 3 in Fig. 6), a template 5 and a measuring cylinder 6 containing a force and a position transducer, which are connected via an electronic system. In each end of the beam are four holes, located 7.5, 9, 10.5 and 12 cm from its midpoint. A pin inserted in one of the holes can be locked in position. The central part of the beam is in the form of a cylinder; into this fits the measuring cylinder which can be moved in relation to the beam and fixed in selected position with the lever 9. The cylinder holder also takes the template 5, by means of which the central pin is inserted in its correct position.

Pins 1 and 3, the outer pins, have a shaft 4 mm in diameter which ends in a needle 18 mm long and 1.5 mm in diameter. This is ground to a point on four sides to give a semi-angle of  $10^\circ$ ; the extreme end of the needle has the form of a cone, to prevent it turning over on insertion into the bone (Fig. 7). The middle pin is essentially the same as the outer pins, except that its shaft is furnished with a guide and a thread so that it can be locked to the shaft of the template or the shaft of the measuring cylinder.

The cylinder constitutes a housing for a position transducer 10 and a force transducer 12. The shaft 11 runs through the position transducer and is connected to the force transducer, to which is also connected a screw with a wheel 13.

The position transducer (Bofors Type RLL-1) is designed for static and dynamic determinations of positions within  $\pm 12$  mm, with a deviation in linearity of  $\pm 0.5$  per cent. The sensory component consists of a differential transformer with a movable core connected in the shaft 11. The calibration values given by the manufacturer are accurate to 0.5 per cent for the temperature range  $10-30^\circ\text{C}$ .

The force transducer (Bofors, Type KRK-2) has a measuring area of range 0 to  $\pm 10$  kgf. The sensory component consists of a metal cylinder, whose axis is perpendicular to the direction of the applied force, and

If the three beams are taken to represent the fractured tibia,  $E_f$ , in eqn. [11], is the modulus of elasticity,  $I_f$  the moment of inertia and  $\delta_f$  the deflection of the callus, which has a very short length of  $s$ .

$\delta_f$  is calculated in the following way. The bone fragments corresponding to the two beams have an observed deflection that is regarded as being equal to the observed deflection of the sound tibia,  $v_t$ . By subtracting  $v_t$  from the observed deflection of the fractured tibia,  $v_{tot}$ , the deflection of the callus is obtained. Thus,

$$\delta_f = v_{tot} - v_t \quad \dots \quad [12]$$

The ratio  $s/E_f$  is a measure of the stability of the callus. Neither  $s$  nor  $I_f$  can be determined. Since the former moment of inertia of the bone should be recovered on healing, the moment of inertia of the callus,  $I_f$ , was considered to be equal to that of the sound tibia at the level corresponding to that of the fracture. It is obtained as a multiple of  $I_{min}$  from the curves for the ratio  $I_{min(x)}/I_{min}$  (Fig. 4, middle).

When a fracture heals the deflection of the callus decreases and  $\delta_f$  approaches zero; thus  $E_f$  approaches very high values.

## STATISTICAL METHODS

In the evaluation of the results the usual statistical methods were applied and the procedures are to be found in *Statistical Methods* by G. W. Snedecor and W. G. Cochran (1967).

The results of the measurements on the right and left tibias or of different methods of measurements were compared by analysis of variance, and the probabilities,  $P$ , of hypotheses set up were determined by means of the  $F$  ratio. Student's  $t$  was used to determine confidence intervals for the observed means.

Linear regression analyses were performed by the method of least squares.

## IV. Methods

### MEASURING INSTRUMENT

The instrument consists of an aluminium beam (4 in Fig. 6), referred to as the "measuring beam", three stainless steel pins (1, 2 and 3 in Fig. 6), a template 5 and a measuring cylinder 6 containing a force and a position transducer, which are connected *via* an electronic system. In each end of the beam are four holes, located 7.5, 9, 10.5 and 12 cm from its midpoint. A pin inserted in one of the holes can be locked in position. The central part of the beam is in the form of a cylinder; into this fits the measuring cylinder which can be moved in relation to the beam and fixed in selected position with the lever 9. The cylinder holder also takes the template 5, by means of which the central pin is inserted in its correct position.

Pins 1 and 3, the outer pins, have a shaft 4 mm in diameter which ends in a needle 18 mm long and 1.5 mm in diameter. This is ground to a point on four sides to give a semi-angle of  $10^\circ$ ; the extreme end of the needle has the form of a cone, to prevent it turning over on insertion into the bone (Fig. 7). The middle pin is essentially the same as the outer pins, except that its shaft is furnished with a guide and a thread so that it can be locked to the shaft of the template or the shaft of the measuring cylinder.

The cylinder constitutes a housing for a position transducer 10 and a force transducer 12. The shaft 11 runs through the position transducer and is connected to the force transducer, to which is also connected a screw with a wheel 13.

The position transducer (Bofors Type RLL-1) is designed for static and dynamic determinations of positions within  $\pm 12$  mm, with a deviation in linearity of  $\pm 0.5$  per cent. The sensory component consists of a differential transformer with a movable core connected in the shaft 11. The calibration values given by the manufacturer are accurate to 0.5 per cent for the temperature range  $10-30^\circ\text{C}$ .

The force transducer (Bofors, Type KRK-2) has a measuring area of range 0 to  $\pm 10$  kgf. The sensory component consists of a metal cylinder, whose axis is perpendicular to the direction of the applied force, and

FIGURE 7 *Left—Outer pin. Centre—Middle pin  
Right—Enlargement of the pin tip showing conical shape of end.*

The signals produced by the position and force transducers are led to an X-Y recorder (Moseley, Model 7035 A), which registers a load-deflection diagram, accuracy  $\pm 0.2$  per cent; linearity  $\pm 0.1$  per cent. The Y coordinate denotes the displacement of the middle pin in relation to the position transducer, and the X coordinate the compressive or tensile force acting on the pin. The instrument can be set so that a full-scale reading on the Y-axis corresponds to a displacement of 0.5, 1, 2, 5 or 10 mm, and the full-scale deflection on the X-axis to a force of 1, 5 or 10 kgf. For most of the measurements in the investigation the full-scale deflection represented 0.5 mm and 5 kgf, respectively.

### PRINCIPLES OF MEASUREMENT

The tibia is loaded by fixing the measuring beam to the bone with the outer pins and applying a bending force between the beam and the bone by means of the screw which moves the middle pin towards or away from the bone.

The method of measurement is based on the principle governing the bending of two beams connected at the ends and subjected to a bending force applied at the midpoint. In the present case one of the beams consists of the tibia and the other of the measuring beam. By regarding the tibia as a beam in the composite mode of loading it is possible to apply the

inside which are four strain gauges, attached at different distances from each other. When loaded, the cylinder is deformed so that its cross section is elliptical and the change in the radius of curvature of the cylinder is registered by the strain gauges, which form a 4-armed measuring bridge. The force transducer is connected to a transducer amplifier indicator, (Bofors, Type BKI-1), which contains circuits for measurement, and for balancing and calibration of the transducer bridge, and an amplifier. The deviation from linearity and hysteresis are less than 0.2 per cent and the calibration accuracy  $\pm 0.5$  per cent.

FIGURE 7 *Left—Outer pin. Centre—Middle pin.

conical shape of end*

The signals produced by the position and force transducers are led to an X-Y recorder (Moseley, Model 7035 A), which registers a load-deflection diagram; accuracy  $\pm 0.2$  per cent; linearity  $\pm 0.1$  per cent. The Y coordinate denotes the displacement of the middle pin in relation to the position transducer, and the X coordinate the compressive or tensile force acting on the pin. The instrument can be set so that a full-scale reading on the Y-axis corresponds to a displacement of 0.5, 1, 2, 5 or 10 mm, and the full-scale deflection on the X-axis to a force of 1, 5 or 10 kgf. For most of the measurements in the investigation the full-scale deflection represented 0.5 mm and 5 kgf, respectively.

## PRINCIPLES OF MEASUREMENT

The tibia is loaded by fixing the measuring beam to the bone with the outer pins and applying a bending force between the beam and the bone by means of the screw which moves the middle pin towards or away from the bone.

The method of measurement is based on the principle governing the bending of two beams connected at the ends and subjected to a bending force applied at the midpoint. In the present case one of the beams consists of the tibia and the other of the measuring beam. By regarding the tibia as a beam in the composite mode of loading it is possible to apply the

inside which are four strain gauges, attached at different distances from each other. When loaded, the cylinder is deformed so that its cross section is elliptical and the change in the radius of curvature of the cylinder is registered by the strain gauges, which form a 4-armed measuring bridge. The force transducer is connected to a transducer amplifier indicator, (Bofors, Type BKI-1), which contains circuits for measurement, and for balancing and calibration of the transducer bridge, and an amplifier. The deviation from linearity and hysteresis are less than 0.2 per cent and the calibration accuracy  $\pm 0.5$  per cent.

FIGURE 9 The measuring instrument bolted to a steel beam used for checking that the deflection at a bending force of 5 kgf lies within the pre-determined limits

beam was bolted (Fig. 9). The same bar was used for measuring the deformation of the measuring beam, as described below.

### MEASURING ERROR

The position transducer indicates the total deflection of the beam and the object when a load is applied. The deflection of the beam was determined by fixing it to a steel bar measuring 32 by 32 by 300 mm made of 1.5 mm sheet steel. It was fixed with pins, the tips of which were soldered to bolts. The outer bolts were connected to the bar at an interval of 24 and 21 cm.

The deflection of the steel bar produced by a bending force of 5 kgf exerted by the middle pin is theoretically  $3.8 \mu\text{m}$  for 24 cm and  $2.5 \mu\text{m}$  for 21 cm. The deflection of the steel bar and the measuring beam with 24 cm between the bolts was  $24.2 \mu\text{m}$  (range 22–27;  $n=11$ ) for 5 kgf, and  $48.5 \mu\text{m}$  (range 44–52;  $n=8$ ) for 10 kgf. With 21 cm between the bolts the deflection was  $14.9 \mu\text{m}$  (range 13–17;  $n=11$ ) for 5 kgf, and  $29.7 \mu\text{m}$  (range 27–32;  $n=11$ ) for a force of 10 kgf.

The total mutual displacement of the tibia and the beam recorded by the position transducer includes the local movement of the cortex around the needles. As a compressive force on the outer pins will result in a tensile force on the middle pin, and *vice versa*, the error due to this local deformation of the bone consists of the displacement of the middle pin and half the sum of the displacement of the outer pins.

FIGURE 8 *The instrument mounted on a fractured tibia. See legend to figure 6.*  
 17 Tibia 18 Fracture.

principle pertaining to the deflection of a straight uniform beam simply supported and loaded at its midpoint.

The load is applied by turning the wheel 13 (Fig. 8) so that the shaft 11 with the middle pin 2 presses against the bone 17. The tibia and the measuring beam are thus bent with their convexities in opposite directions with a compressive force  $P$ ; the reaction  $P/2$  produces a tensile stress in each outer pin. When the measuring beam and the bone are deflected in this way the outer pins, which are locked in the beam and fixed in the bone, will bend with their convexities towards the middle pin; when the shaft 11 is subjected to a tensile force, the opposite loading conditions will obtain, so that the tibia and the measuring beam are bent towards each other. The deflection is thus measured in both positive and negative directions.

### CALIBRATION

The X-Y recorder was connected to the position and force transducers and the instruments were calibrated and the linearity was checked over various measuring ranges. On several occasions during the course of the investigation the force transducer was calibrated against a load of 5 kgf and the reading on the X-Y recorder was checked. The position transducer was checked with the aid of pieces of sheet metal, whose dimensions had been determined with a micrometer screw gauge. No corrections were required during the course of this investigation. The instrument was also calibrated in a simpler way—against a steel bar to which the measuring

articular space of the knee or the medial malleolus. A local anaesthetic is administered at the intended sites in the skin and down towards the periosteum. The correct location of the anaesthetic is ensured by using the template 14 (Fig. 6), which consists of a stainless steel strip with holes corresponding to the positions of the middle pin and the pin distances on the measuring beam.

The outer pins are inserted in the holes in the beam and locked by gentle tightening of the wheels 7 and 8. On the shaft of the template 5 the middle pin is fixed and the template inserted in its cylindrical holder. The pins are placed perpendicular to the medial surface on the tibia. With a light tap of a hammer the pins are inserted through the skin and periosteum down to the bone surface. The wheels 7 and 8 are then loosened and while the beam is held in one hand the pins are hammered about 2 mm into the cortex. They must be securely held by the bone but not penetrate to the marrow space. The outer pins are inserted first, followed by the middle one. The outer pins are locked to the measuring beam by tightening the wheels 7 and 8. The nut on the shaft passing through the template is unscrewed from the middle pin, and the template with the shaft removed. After the position and force transducers have been set at zero, the measuring cylinder is locked to the middle pin by the nut on the shaft with the aid of spanners 15 and 16. When the measuring cylinder is in place it is locked to the beam by tightening the lever 9. As the measuring cylinder cannot be sterilized, from now onwards the sterility in the investigation is broken and the greatest care must be observed to avoid infection of the small lesions due to the

FIGURE 10 *The measuring instrument applied to the bone in the living patient for measurement of deflection. On the right is the X-Y recorder, and below it the transducer, amplifier, and bridge.*

The deformation of the actual pins also constitutes a source of error, but in measurements on bone this does not amount to as much as 1 per cent of the total deformation.

The sum of the deformation of the measuring beam, of the cortex around the pins and of the pins themselves was determined as follows. Twelve tibia specimens were sawn through their length, ground plane on the surface that was to be placed against the steel bar, and fixed to this bar with six bolts. Each specimen was tested twice at the two pin distances 24 and 21 cm. ("Pin distance" refers to the distance between the outer pins.) The deflection in the negative and positive directions produced by a load of 5 kgf was determined five times in each direction. There was no difference in the deflections in the two directions; the mean for the pin distance of 24 cm was 42.9  $\mu\text{m}$  (range 32—63) and for 21 cm it was 31.3  $\mu\text{m}$  (range 22—41). These values *minus* the deflection of the steel bar for the respective pin distances gives the correction to be subtracted from the observed measured displacement in an examination of the deflection of the bone. For a force of 5 kgf the corrections were 39  $\mu\text{m}$  and 29  $\mu\text{m}$  with 24 and 21 cm between the outer pins.

### MEASURING TECHNIQUE

The instrument is intended for use in diaphyseal fractures of the long bones. The tibia was chosen for the investigation because fractures of this bone are common and not infrequently display delayed union.

The level at which the instrument shall be placed on the tibia is decided by the position of the fracture. The deflection is greater the closer the middle pin is to the fracture; this distance should not be less than 2 cm, because during the union the cortex becomes softer and does not provide so firm a hold for the pin. The mean distance from the centre of the fracture to the pin was 60 mm. For extreme distal or proximal sites of fracture an outer pin may have to be placed in the malleolar and condylar part of the tibia; here the cortex is thin and there is a risk that the pin will not be held firmly enough. There is also a risk that when it is being inserted the cortex may easily be penetrated, with consequent weakening of the hold.

In such cases, it would be wiser to use a distance of 21 cm or less, but for the sake of uniformity in the assessment of the results 24 cm was used in all but two cases, and here the distance was 21 cm.

When the level at which the instrument is to be placed has been determined it is marked on the fractured leg, and also on the sound leg. The level of the middle pin was measured as the distance from the medial

articular space of the knee or the medial malleolus. A local anaesthetic is administered at the intended sites in the skin and down towards the periosteum. The correct location of the anaesthetic is ensured by using the template 14 (Fig. 6), which consists of a stainless steel strip with holes corresponding to the positions of the middle pin and the pin distances on the measuring beam.

The outer pins are inserted in the holes in the beam and locked by gentle tightening of the wheels 7 and 8. On the shaft of the template 5 the middle pin is fixed and the template inserted in its cylindrical holder. The pins are placed perpendicular to the medial surface on the tibia. With a light tap of a hammer the pins are inserted through the skin and periosteum down to the bone surface. The wheels 7 and 8 are then loosened and while the beam is held in one hand the pins are hammered about 2 mm into the cortex. They must be securely held by the bone but not penetrate to the marrow space. The outer pins are inserted first, followed by the middle one. The outer pins are locked to the measuring beam by tightening the wheels 7 and 8. The nut on the shaft passing through the template is unscrewed from the middle pin, and the template with the shaft removed. After the position and force transducers have been set at zero, the measuring cylinder is locked to the middle pin by the nut on the shaft with the aid of spanners 15 and 16. When the measuring cylinder is in place it is locked to the beam by tightening the lever 9. As the measuring cylinder cannot be sterilized, from now onwards the sterility in the investigation is broken and the greatest care must be observed to avoid infection of the small lesions due to the

FIGURE 10 *The measuring instrument applied to the bone in the living patient for measurement of deflection. On the right is the X-Y recorder, and below it the transducer, amplifier, and bridge.*

pins. The legs rest on a foam rubber cushion, usually slightly everted so that the instrument is perpendicular and rests on the bone, or else it is steadied with one hand (Fig. 10).

The instrument is now ready for measurement of the load on, and deflection of, the tibia. When the wheel of the cylinder is turned clockwise the middle pin moves down to bear on to the bone and the X-Y recorder registers a curve in the negative direction of  $x$ . The wheel is turned until a full reading corresponding to a compressive force of 1, 5 or 10 kgf is obtained on the middle pin, which produces a deflection in the negative direction. By turning the wheel counterclockwise the compressive force on the middle pin is first decreased to zero and then a tensile force is produced until a full-scale deflection is obtained in the positive direction of  $x$ . Examples of the curves recorded for the tibia specimens are shown in figure 11.

It is important to ensure that the pins do not loosen during the measurements. To avoid disturbing the outer pins while the middle pin is being hammered in they should not be locked until afterwards. If a pin penetrates the cortex it may slide in relation to the bone. Curve C in figure 12 shows how a change on the position of the middle pin by turning the wheel on the measuring cylinder results in an increase in the reading from the position

FIGURE 11 *Load-deflection curve for tibia specimen*

FIGURE 12 Load-deflection curve for vital tibia.

- A—Curve showing hysteresis due to high friction of measuring cylinder shaft against position transducer owing to oblique middle pin
- B—Because the pin had loosened the curves tend towards the axis of  $y$  after an initial short increase in deflection.
- C—Slipping of the pin produced a large displacement parallel to the axis of  $y$ , with no change in applied force

transducer—that is along the  $y$ -axis of the recorder—but no increase in the force already applied, which remains constant at a value of  $x$  corresponding to the force required to overcome the frictional resistance of the pin in the bone.

When a pin loosens, the stress in the beam is relieved and the beam recovers its original shape, the resulting displacement producing an increase in deflection. The force on the middle pin is also relieved and  $x$  again be-

pins. The legs rest on a foam rubber cushion, usually slightly everted so that the instrument is perpendicular and rests on the bone, or else it is steadied with one hand (Fig. 10).

The instrument is now ready for measurement of the load on, and deflection of, the tibia. When the wheel of the cylinder is turned clockwise the middle pin moves down to bear on to the bone and the X-Y recorder registers a curve in the negative direction of  $x$ . The wheel is turned until a full reading corresponding to a compressive force of 1, 5 or 10 kgf is obtained on the middle pin, which produces a deflection in the negative direction. By turning the wheel counterclockwise the compressive force on the middle pin is first decreased to zero and then a tensile force is produced until a full-scale deflection is obtained in the positive direction of  $x$ . Examples of the curves recorded for the tibia specimens are shown in figure 11.

It is important to ensure that the pins do not loosen during the measurements. To avoid disturbing the outer pins while the middle pin is being hammered in they should not be locked until afterwards. If a pin penetrates the cortex it may slide in relation to the bone. Curve C in figure 12 shows how a change on the position of the middle pin by turning the wheel on the measuring cylinder results in an increase in the reading from the position

FIGURE 11 *Load-deflection curve for tibia specimen*

The magnitude of the deflection within the fracture is strongly dependent on its distance from the nearer outer pin. On films of the fractured tibia the distance from the middle pin to the line of fracture is measured in the projection that gives a side view of the pins. Two distances are determined, namely, that from the middle pin to the fracture line on the same side as the pin is inserted, and that to the fracture line in the cortex of the opposite side. The distance from the centre of the fracture to the level of the middle pin is calculated as half the sum of the above two distances multiplied by the enlargement factor. The distance so obtained subtracted from the distance between the middle pin and the relevant outer pin gives the distance from the nearer outer pin to the fracture— $l$  in eqn. [11].

The moment of inertia for the narrowest part of the sound tibia shaft is calculated. On films taken with the projection giving a lateral view of the pins the narrowest part of the tibia is found, and as far distally as possible within this part measurements are made of the distance  $d$ , the thickness of the tibia to the medial surface. The diameter  $a$  of the marrow space at the same level is also determined. The distance of the middle pin from this level in this projection is marked off from the middle pin on the radiograph exposed with the perpendicular projection, and here the width  $b$  of the tibia is determined.

The dimensions so obtained are corrected with respect to the enlargement factor and entered in eqn. [8].  $I_{app} = 0.042 bd^3 - 0.049 a^4$ , which gives an approximate value of the moment of inertia of the tibia at its narrowest part.

comes zero. Curves B in figure 12 recorded when a pin loosened show how the force diminishes and the curves run parallel with the  $x$ -axis towards zero.

When the middle pin is being inserted it may bend or be guided along an oblique path in the bone substance. This is indicated by difficulty in getting the measuring cylinder into position on the middle pin, it being necessary to move its head slightly to the side before the shaft of the measuring cylinder can be screwed fast. This, however, will result in too large a deflection, since the position transducer also registers any deformation of the pin. The error will be greatest if the deviation of the middle pin from the plane of deflection of the instrument occurs in the transverse plane of the tibia, because then a torque will be produced that will also tend to bend the outer pins in a transverse plane. While a middle pin is inclined in the bending plane of the tibia it will not tend to rotate the bone. This situation is reflected in a curve as an increase in hysteresis. It is due to the fact that the axis of the measuring cylinder bears against the housing of the position transducer, and the force required to overcome the resulting friction is recorded without simultaneous change in the position of the axis; this is illustrated by curve A in figure 12.

When the measurement is completed the nut holding the middle pin is loosened and the lever 9 and the measuring cylinder are removed. The outer pins are unlocked and the beam lifted off.

The measuring procedure is then repeated on the sound leg and radiographs are taken with all the pins in place in both tibias.

## RADIOGRAPHIC EXAMINATION

After the measurements radiographs are taken with the exposure data kept constant for each patient. On the radiographs an estimate of the distance between the pins and the fracture is obtained and the dimensions of the tibia are measured for the determination of the moment of inertia; they also serve for the usual examination of the fracture. The radiographs are taken in two projections, one perpendicular to the pins and in the plane of the medial surface of the tibia, and the other parallel to the pins. The central ray is centred on the middle pin. As the distance between the outer pins is known a reliable enlargement factor can be obtained by measuring the distance on the radiograph. By means of this factor the dimensions of the tibia and the distance of the pins from the fracture can be accurately determined.

The magnitude of the deflection within the fracture is strongly dependent on its distance from the nearer outer pin. On films of the fractured tibia the distance from the middle pin to the line of fracture is measured in the projection that gives a side view of the pins. Two distances are determined, namely, that from the middle pin to the fracture line on the same side as the pin is inserted, and that to the fracture line in the cortex of the opposite side. The distance from the centre of the fracture to the level of the middle pin is calculated as half the sum of the above two distances multiplied by the enlargement factor. The distance so obtained subtracted from the distance between the middle pin and the relevant outer pin gives the distance from the nearer outer pin to the fracture— $l$  in eqn. [11].

The moment of inertia for the narrowest part of the sound tibia shaft is calculated. On films taken with the projection giving a lateral view of the pins the narrowest part of the tibia is found, and as far distally as possible within this part measurements are made of the distance  $d$ , the thickness of the tibia to the medial surface. The diameter  $a$  of the marrow space at the same level is also determined. The distance of the middle pin from this level in this projection is marked off from the middle pin on the radiograph exposed with the perpendicular projection, and here the width  $b$  of the tibia is determined.

The dimensions so obtained are corrected with respect to the enlargement factor and entered in eqn. [8].  $I_{\text{tibia}} = 0.042 bd^3 - 0.049 a^4$ , which gives an approximate value of the moment of inertia of the tibia at its narrowest part.

comes zero. Curves B in figure 12 recorded when a pin loosened show how the force diminishes and the curves run parallel with the  $x$ -axis towards zero.

When the middle pin is being inserted it may bend or be guided along an oblique path in the bone substance. This is indicated by difficulty in getting the measuring cylinder into position on the middle pin, it being necessary to move its head slightly to the side before the shaft of the measuring cylinder can be screwed fast. This, however, will result in too large a deflection, since the position transducer also registers any deformation of the pin. The error will be greatest if the deviation of the middle pin from the plane of deflection of the instrument occurs in the transverse plane of the tibia, because then a torque will be produced that will also tend to bend the outer pins in a transverse plane. While a middle pin is inclined in the bending plane of the tibia it will not tend to rotate the bone. This situation is reflected in a curve as an increase in hysteresis. It is due to the fact that the axis of the measuring cylinder bears against the housing of the position transducer, and the force required to overcome the resulting friction is recorded without simultaneous change in the position of the axis; this is illustrated by curve A in figure 12.

When the measurement is completed the nut holding the middle pin is loosened and the lever 9 and the measuring cylinder are removed. The outer pins are unlocked and the beam lifted off.

The measuring procedure is then repeated on the sound leg and radiographs are taken with all the pins in place in both tibias.

## RADIOGRAPHIC EXAMINATION

After the measurements radiographs are taken with the exposure data kept constant for each patient. On the radiographs an estimate of the distance between the pins and the fracture is obtained and the dimensions of the tibia are measured for the determination of the moment of inertia; they also serve for the usual examination of the fracture. The radiographs are taken in two projections, one perpendicular to the pins and in the plane of the medial surface of the tibia, and the other parallel to the pins. The central ray is centred on the middle pin. As the distance between the outer pins is known a reliable enlargement factor can be obtained by measuring the distance on the radiograph. By means of this factor the dimensions of the tibia and the distance of the pins from the fracture can be accurately determined.

tent was retained and for only short intervals were they exposed to the room atmosphere. To reduce evaporation from the bone a thin layer of the investing soft tissues was left in place as long as possible. The actual measurement was performed at room temperature. The directions given by Sedlin (1965) and Sedlin & Hirsch (1966) for preserving the physical properties were followed.

### DETERMINATION OF DEFLECTION

The length of the tibia was taken as the distance between the distal articular surface of the bone and the middle portion of the articular surface of the medial condyle. To obtain the midpoint of the tibia, one half this distance was then marked off from these articular surfaces on the medial surface. The lengths of the specimens are given in table 2. The middle pin of the instrument was anchored at a point half way along and across the tibia, perpendicular to the medial surface (Fig. 13). One measurement was

FIGURE 13 *Measuring instrument applied to a bone specimen*

made with each of the pin intervals 24 and 21 cm. The middle pin was subjected to alternately tensile and compressive forces of up to 5 kgf—both away from and towards the measuring beam (positive and negative directions). No difference in the deflection for these two directions was recorded. Each measurement was repeated five times in both directions and the mean deflection for the 10 measurements for a load of 5 kgf was determined. The recorded curves for a tibia are presented in figure 11.

It was impossible to determine the error of deflection for a single specimen by replicate measurements because for the second measurement the experimental conditions are different. For example, any alteration in the fixation of the pins would result in a change in the plane of bending and the moment of inertia. The error of deflection for a single observation was therefore determined in two ways, namely by measuring the deflection at pin distances of 24 and 21 cm and by comparing the deflections on pairs of

## V. Measurements on autopsy tibias

One of the objects of the experiments on autopsy specimens was to determine the error contained by the recorded value of the deflection of the tibia in a single observation. Another was to check the agreement between the values of the moment of inertia determined by (i) numerical integration, (ii) with an integrator and (iii) by application of eqn. [8] for  $I_{appr}$ .

### MATERIAL

The pairs of tibia specimens were obtained at autopsies performed at the National Forensic Station from persons that had died through trauma or suicide and that, so far as was known, had not had any disease that may have affected the bones. The mean age of these subjects was 32 years (range 22—44). Other data are presented in table 1.

The fresh bone specimens were preserved in Ringer's solution. The deflection measurements were usually performed on the day the specimens were prepared, and never later than the following day. Pending some later examination they were stored at  $-20^{\circ}\text{C}$  in polythene bags containing Ringer's solution. Throughout the work on the specimens the moisture con-

tent was retained and for only short intervals were they exposed to the room atmosphere. To reduce evaporation from the bone a thin layer of the investing soft tissues was left in place as long as possible. The actual measurement was performed at room temperature. The directions given by Sedlin (1965) and Sedlin & Hirsch (1966) for preserving the physical properties were followed.

### DETERMINATION OF DEFLECTION

The length of the tibia was taken as the distance between the distal articular surface of the bone and the middle portion of the articular surface of the medial condyle. To obtain the midpoint of the tibia, one half this distance was then marked off from these articular surfaces on the medial surface. The lengths of the specimens are given in table 2. The middle pin of the instrument was anchored at a point half way along and across the tibia, perpendicular to the medial surface (Fig. 13). One measurement was

FIGURE 13 *Measuring instrument applied to a bone specimen*

made with each of the pin intervals 24 and 21 cm. The middle pin was subjected to alternately tensile and compressive forces of up to 5 kgf—both away from and towards the measuring beam (positive and negative directions). No difference in the deflection for these two directions was recorded. Each measurement was repeated five times in both directions and the mean deflection for the 10 measurements for a load of 5 kgf was determined. The recorded curves for a tibia are presented in figure 11.

It was impossible to determine the error of deflection for a single specimen by replicate measurements because for the second measurement the experimental conditions are different. For example, any alteration in the fixation of the pins would result in a change in the plane of bending and the moment of inertia. The error of deflection for a single observation was therefore determined in two ways, namely by measuring the deflection at pin distances of 24 and 21 cm and by comparing the deflections on pairs of

## V. Measurements on autopsy tibias

tibias. In the former method it should be possible to keep the same plane of bending.

No measurements were made for the 21-cm distance for either tibia of subject no. 1, nor for the right tibia of subject no. 4. The marked hysteresis displayed by the curves for subject no. 9, left tibia, 24-cm pin distance, is due to an oblique position of the middle pin, and the value for this curve was therefore discarded.

The values of  $\delta_{21}$  and  $\delta_{21}$  obtained after correction for the error of the method (instrument deformation, page 24) are given in table 2.

### DETERMINATION OF THE MOMENT OF INERTIA

The magnitude of the deflection is dependent on the moment of inertia  $I$  and the modulus of elasticity  $E$  of the bone, and to enable a comparison of the deflection of different bones to be made the moment of inertia of the cross section was determined. This was done in three ways: (i) numerical integration, (ii) with an integrator and (iii) by using eqn. [8]. The transverse section of the tibia was chosen at the level where the thickness of the bone  $d$  was smallest and the moment of inertia of the section therefore lowest (page 13).

To obtain as accurate a comparison as possible of the deflection of different tibias the first two methods were used for replicate determinations of the moment of inertia.

#### (i) Numerical integration

The moment of inertia was determined numerically ( $I_{min}$ ) from ink impressions of the cross section of tibia obtained on graph paper. The cross section had previously been ground plane on water-resistant sandpaper under water and the fat in the marrow space and the looser spongy bone scraped away. The section was placed so that the side included in the medial surface was parallel to one of the set lines of the graph paper. For each section the moment of inertia about the central axis was calculated twice, this was done by summing the products of the square of the distance of each millimetre square in the section area from the central axis, and adding to this total the sum of the moment of inertia of each millimetre square about its own central axis. The mean of the two values of the moment ( $I_{min}$ ) is given in table 2.

#### (ii) Integrator

The cross section of the tibia was photographed with a millimetre scale placed in the same plane. The films were copied and enlarged by a factor

TABLE 3 Analysis of variance for the corrected deflections of tibia specimen. The values of  $\delta_{21}$  and  $1.49 \delta_{21}$  are analysed. The values of  $\delta_{21}$  and  $\delta_{21}$  are given in table 2

Source of variation	Degrees of freedom	Mean square	F ratio	P
Specimen	35	866	$F_{1,35} = 1.81$	$> 0.05$
Pin distance	1	65		
Error and interaction*	35	36		

\*Relative error for a single measurement:  $100(36)^{1/2}/75 = \pm 8$  per cent

There was no significant difference between  $\delta_{21}$  and  $1.49 \delta_{21}$ . The relative experimental error for a single determination of the deflection was thus  $\pm 8$  per cent.

The experimental error incurred in measuring the deflection was also determined in another way. The modulus of elasticity was then assumed to be the same for the two tibias of a subject. The relative error of the modulus of elasticity is equal to the square root of the sum of the squares of the relative errors of the moment of inertia and the deflection, as the modulus of elasticity is related to the product of the deflection and the moment of inertia, according to eqn. [2]. Thus, the error in the corrected observed deflection of the tibia can be calculated if the relative errors of the determinations of the modulus of elasticity and the moment of inertia are known. The apparent modulus of elasticity " $E_{21}$ " and " $E_{21}$ " was calculated from the mean value of  $I_{min \text{ i corr}}$  and  $I_{min \text{ n}}$  for each specimen, and the corresponding values of the deflections  $\delta_{21}$  and  $\delta_{21}$ . In the analysis of variance for the determination of the experimental error, the same model as in the previous experiment was used. The two factors were the subject and the side. The interaction between subject and side could not be isolated from the error of measurement. The analyses of variance presented in table 4 show no significant difference between the right and left sides for either " $E_{21}$ " or " $E_{21}$ ". The means for " $E_{21}$ " and " $E_{21}$ " were  $2.6 \times 10^3$  and  $2.4 \times 10^3$  kgf/mm<sup>2</sup>, respectively. The corresponding experimental relative errors were  $\pm 8$  and  $\pm 9$  per cent.

The experimental relative error in determining the moment of inertia was  $\pm 4$  per cent, as reported below. For the mean of two determinations of  $I_{min \text{ i corr}}$  and  $I_{min \text{ n}}$ , as used in the calculation of the apparent modulus of elasticity, the corresponding relative error will be  $\pm 3$  per cent. Thus, the relative error for a single measurement in  $\delta_{21}$  was obtained as  $\pm 7$  per cent and in  $\delta_{21}$  as  $\pm 8$  per cent.

of 10 and the moment of inertia was ( $I_{min\ n}$ ) determined with an Amsler integrator Type 2002. The method error for the integrator is  $\pm 1$  per cent for the measurement of area and  $\pm 2$  per cent for moment of inertia. The sections were placed so that the side included in the medial surface was parallel with the integrator ruler. Two determinations of  $I_{min\ t}$  were made on each section; their mean and the corrected values of  $I_{min\ t}$ , designated ( $I_{min\ t\ corr}$ ), are given in table 2. The correction takes account of non-uniform enlargement.

### (iii) Formula

On the photographic enlargements of the sections produced for method (ii) measurements were made of the depth of the tibia ( $d$ ), the width of the section ( $b$ ) and the diameter of the marrow space ( $a$ ), as these dimensions would be obtained by radiographic projection by the technique mentioned on page 29. These values were inserted in eqn. [8] for the approximate moment of inertia:  $I_{min\ appr} = 0.042\ bd^3 - 0.049\ a^4$ .

## RESULTS

### Deflection

As is evident from eqn [9], if the tibia is regarded as a simply supported beam loaded at its midpoint, the corrected deflections,  $\delta_{21}$  and  $\delta_{21}$ , are related as the cubes of the respective outer pin distances multiplied by the constants 1/67 and 1/66, respectively. The theoretical ratio of  $\delta_{21}$  and  $\delta_{21}$  is then determined thus:  $(24.1^3/67)/(21.0^3/66)$ , or 1.49. By dividing the value of  $\delta_{24}$  by that of  $\delta_{21}$  from each specimen, an experimental value for the ratio was obtained. A preliminary analysis disclosed no difference between the quotients for the right and the left tibias. The mean for all 36 specimens was then 1.46. The theoretical ratio lay within the 99 per cent confidence interval for the experimental ratio.

By multiplying  $\delta_{21}$  by the theoretical ratio 1.49, a value is obtained that can be compared with  $\delta_{24}$ . The series of values  $\delta_{24}$  and  $1.49\ \delta_{21}$  were submitted to analysis of variance to determine the experimental error incurred in the deflection of the tibia (Table 3). As it was only the values for one and the same bone that were compared, determinations on both right and left tibias could be used in the determination of the measurement error. In the analysis of variance the two series of deflection values from the tibias were treated as a two-factor experiment, the two factors being the specimen and the pin distance (*Snedecor & Cochran*, Chapter 12). However, the sum of the squares of interaction cannot be separated from the sum of the squares of the error (Table 3).

TABLE 5 Analysis of variance for the minimum moment of inertia of the narrowest tibia section derived from values of  $I_{min\ app}$  and  $I_{min\ t}$  (Table 2)

Source of variation	Degrees of freedom	Mean square	F ratio	P
Side, I	1	0.00437	$F_{1,19} = 0.55$	>0.05

" I & III	19	0.00500	$F_{19,19} = 6.85$	<0.001
Error and interaction* I, II & III	19	0.00073		

\*Relative error for a single determination  $100(0.00073)^{1/2}/0.91 = \pm 3$  per cent

Means  $I_{min\ app} = 0.92$ ;  $I_{min\ t} = 0.89\text{ cm}^4$

In exactly the same manner the values of the moments of inertia arrived at by numerical integration ( $I_{min\ n}$ ) and the corrected values obtained by the integrator method ( $I_{min\ t\ corr}$ ) were analysed. These two series of values are presented in table 2, and the results of the analysis of variance are given in table 6. There was no significant difference between sides or between methods. A highly significant lack of additivity between side and subject was obtained but in this experiment there was no significant lack of additivity between method and subject.

The approximation method for determining the moment of inertia contains an error the magnitude of which increases with the disparity between

TABLE 6 Analysis of variance for the minimum moment of inertia of the narrowest tibia section derived from values of  $I_{min\ t\ corr}$  and  $I_{min\ n}$  (Table 2)

Source of variation	Degrees of freedom	Mean square	F ratio	P
Side, I	1	0.02034	$F_{1,19} = 2.85$	>0.05
Method, II	1	0.0185	$F_{1,19} = 1.45$	>0.05
Subject, III	19	0.32696		
Interaction, I & II	1	0.00001		
" I & III	19	0.00713	$F_{19,19} = 5.17$	<0.001
" I & III	19	0.00123	$F_{19,19} = 0.93$	>0.05
Error and interaction* I, II & III	19	0.00138		

\*Relative error for a single determination  $100(0.00138)^{1/2}/0.89 = \pm 4$  per cent

Means  $I_{min\ t\ corr} = 0.89$ ,  $I_{min\ n} = 0.90\text{ cm}^4$

TABLE 4 *Analysis of variance for the apparent modulus of elasticity of the tibia specimens. Separate analyses were performed for the pin distances 24 and 21 cm*

	Degrees of freedom	Mean square $\times 10^6$	F ratio	P
PIN DISTANCE 24 cm				
Source of variation				
Subject	18	3048	$F_{1;18}=1.61$	$>0.05$
Side	1	679		
Error and interaction <sup>a</sup>	18	423		
PIN DISTANCE 21 cm				
Subject	17	2385	$F_{1;17}=0.88$	$>0.05$
Side	1	455		
Error and interaction <sup>b</sup>	17	519		

<sup>a</sup>Relative error for a single determination:  $100(423 \times 10^6)^{1/2} / 258,000 = \pm 8$  per cent

<sup>b</sup> " " " " " :  $100(519 \times 10^6)^{1/2} / 241,000 = \pm 9$  per cent

Thus, the relative error of the deflection of the tibia for a single determination was  $\pm 8$  per cent for both methods of determining the experimental error.

### *Moment of inertia*

The values obtained for the moment of inertia from eqn [8]  $I_{min\ app}$  and from the determination with the integrator  $I_{min}$ , were compared (Table 2). As they were determined from the same enlarged photographs, no refined correction for the small difference in the enlargement factor between different pictures is necessary. By analysis of variance, the factors considered to influence the measurements were examined. The main sources of variation were side (I), method (I) and subject (III). There was also the interaction between side and method (I & II), side and subject (I & III), and method and subject (II & III) and the three-factor interaction (I, II & III) could not be separated from the experimental error. Statistical models are given in *Snedecor & Cochran*, Chapter 12.

The analysis of variance (Table 5) shows that there is no significant difference between sides or methods and there is a highly significant lack of additivity between side and subject and also between method and subject. The estimated relative error for a single determination of  $I_{min\ app}$  is  $\pm 3$  per cent.

TABLE 7 Angle  $\beta$  between chosen plane of bending for the instrument and the bending plane for the minimum moment of inertia. Increase in the moment of inertia corresponding to observed angle  $\beta$ . Ratio  $I_{\max}/I_{\min}$

Angle $\beta$ between chosen and principal central axis; degrees	Subject	1	2	3	5	13	14	18
$\beta - I_{\min}$	7.3	-0.5	1.5	9.3	7.8	-1.5	<0.1	
as a percentage of $I_{\min}$	1.4	<0.1	<0.1	2.2	0.5	0.2	<0.1	
$I_{\max}/I_{\min}$	1.85	1.29	1.54	1.96	1.28	2.56	1.79	

The deflection curve of a particular tibia is unique. As pointed out on page 15, this curve is dependent on the variation of the minimum moment of inertia for the section along the length of tibia. If the weakest section were to be located at the level of the middle pin, this would be the site of the greatest possible deflection of the tibia. As the centre of torsion and the centroid of the tibia section do not coincide, the deflection of the tibia will be combined with a rotation. The calculations show that in the least favourable case the error in the recorded deflection due to this rotation does not amount to more than +2 per cent.

#### *Factors governing the moment of inertia*

The moment of inertia is difficult to measure in spongy bone, but the narrowest part of the tibia contains only a small amount of such substance. It is difficult to draw a boundary between the cortical and the spongy bone, and the border has been chosen where the cavities of the narrowest part of the tibia the spongy bone occupies an increasingly large proportion of the section, and it is difficult to judge its share of the moment of inertia. For other than the narrowest part, it is thus mainly the moment of inertia of the cortical bone that was determined. This means that the value for the sections with a greater proportion of spongy bone is on the low side.

Compact bone varies in porosity and there are divergent opinions on the effect of this structural factor on the physical properties of the bone (Evans, 1958; Smith & Walmsley, 1958; Currey, 1959; Vose, 1961; Sedlin & Hirsch, 1966; Blaimont, 1968; Evans & Bang, 1968). The fact that the subjects from which the bone specimens were obtained were not above 44 years of age would seem to rule out the possibility of osteoporosis and the specimens probably did not differ essentially in porosity.

the configuration of the cross section and that of the standardized contour. This explains why the mean square of the interaction between method and subject is larger in the analysis of  $I_{min\ appr}$  and  $I_{min\ t}$  than in that of  $I_{min\ t\ corr}$  and  $I_{min\ n}$ .

## DISCUSSION

### *Factors affecting the deflection*

The maximum deflection of the tibia is obtained if the bending force acts in the bending plane for the minimum moment of inertia of the section. Since the directions of the principal central axes are unknown at the time of the measurement, the recorded deflection will include the error due to the instrument being placed perpendicular to the medial surface of the tibia. If the direction of the load makes an angle  $\beta$  with the plane for maximum deflection of the tibia the bending will occur in a plane making an angle of  $\varphi$  with the plane for maximum deflection, where the relationship between these angles is given by eqn. [6]. The deviation of the recorded deflection from the maximum is obtained from eqn. [7]. By way of example, consider the case where  $\beta=15^\circ$ ,  $I_{max}=1.5$  and  $I_{min}=1.0$ ; then  $\varphi=10.1^\circ$ . These values entered in the formula give  $v_{obs}=0.977\ v_{max}$ . The recorded deflection of the tibia is thus 2.3 per cent smaller than the maximum deflection as a result of the angle between the plane perpendicular to the plane of the medial surface and the plane for maximum deflection of the tibia. As this angle will probably not exceed  $15^\circ$ , the given example will illustrate the influence of the angle between the planes on the error of the deflection in a most unfavourable case.

To see how the angle between the plane perpendicular to the medial surface and the bending plane for maximum deflection of tibia varies, the directions of the principal central axis of seven sections of widely different shapes were examined. The direction of one of the principal central axes lies in the plane for maximum deflection of the tibia. By means of the integrator the principal moment of inertia and the positions of the principal central axes were determined. The greatest value of the required angle was  $9.3^\circ$ , which implies an increase of 2.2 per cent in the corresponding moment of inertia from the minimum moment. The results from the other sections are given in table 7. The highest value for the ratio  $I_{max}/I_{min}$  was 2.6.

According to the determinations performed on autopsy specimens, the principal central axes in different sections are practically parallel (Fig. 3), and the tibia would thus not itself produce a rotation while being bent.

TABLE 7 *Angle  $\beta$  between chosen plane of bending for the instrument and the bending plane for the minimum moment of inertia. Increase in the moment of inertia corresponding to observed angle  $\beta$ . Ratio  $I_{\max}/I_{\min}$*

	Subject	1	2	3	5	13	14	18
Angle $\beta$ between chosen and principal central axis; degrees		7.3	-0.5	1.5	9.3	7.8	-1.5	<0.1
$I\beta - I_{\min}$								
as a percentage of $I_{\min}$		1.4	<0.1	<0.1	2.2	0.5	0.2	<0.1
$I_{\max}/I_{\min}$		1.85	1.29	1.54	1.96	1.28	2.56	1.79

The deflection curve of a particular tibia is unique. As pointed out on page 15, this curve is dependent on the variation of the minimum moment of inertia for the section along the length of tibia. If the weakest section were to be located at the level of the middle pin, this would be the site of the greatest possible deflection of the tibia.

As the centre of torsion and the centroid of the tibia section do not coincide, the deflection of the tibia will be combined with a rotation. The calculations show that in the least favourable case the error in the recorded deflection due to this rotation does not amount to more than +2 per cent.

#### *Factors governing the moment of inertia*

The moment of inertia is difficult to measure in spongy bone, but the narrowest part of the tibia contains only a small amount of such substance. It is difficult to draw a boundary between the cortical and the spongy bone, and the border has been chosen where the cavities of the spongy bone merge with the marrow space. Proximally and distally of the narrowest part of the tibia the spongy bone occupies an increasingly large proportion of the section, and it is difficult to judge its share of the moment of inertia. For other than the narrowest part, it is thus mainly the moment of inertia of the cortical bone that was determined. This means that the value for the sections with a greater proportion of spongy bone is on the low side.

Compact bone varies in porosity and there are divergent opinions on the effect of this structural factor on the physical properties of the bone (Evans, 1958; Smith & Walmsley, 1958; Currey, 1959; Vose, 1961; Sedlin & Hirsch, 1966; Blaimont, 1968; Evans & Bang, 1968). The fact that the subjects from which the bone specimens were obtained were not above 44 years of age would seem to rule out the possibility of osteoporosis and the specimens probably did not differ essentially in porosity.

the configuration of the cross section and that of the standardized contour. This explains why the mean square of the interaction between method and subject is larger in the analysis of  $I_{min\ appr}$  and  $I_{min\ t}$  than in that of  $I_{min\ t\ corr}$  and  $I_{min\ n}$ .

## DISCUSSION

### *Factors affecting the deflection*

The maximum deflection of the tibia is obtained if the bending force acts in the bending plane for the minimum moment of inertia of the section. Since the directions of the principal central axes are unknown at the time of the measurement, the recorded deflection will include the error due to the instrument being placed perpendicular to the medial surface of the tibia. If the direction of the load makes an angle  $\beta$  with the plane for maximum deflection of the tibia the bending will occur in a plane making an angle of  $\varphi$  with the plane for maximum deflection, where the relationship between these angles is given by eqn. [6]. The deviation of the recorded deflection from the maximum is obtained from eqn. [7]. By way of example, consider the case where  $\beta=15^\circ$ ,  $I_{max}=1.5$  and  $I_{min}=1.0$ ; then  $\varphi=10.1^\circ$ . These values entered in the formula give  $v_{obs}=0.977\ v_{max}$ . The recorded deflection of the tibia is thus 2.3 per cent smaller than the maximum deflection as a result of the angle between the plane perpendicular to the plane of the medial surface and the plane for maximum deflection of the tibia. As this angle will probably not exceed  $15^\circ$ , the given example will illustrate the influence of the angle between the planes on the error of the deflection in a most unfavourable case.

To see how the angle between the plane perpendicular to the medial surface and the bending plane for maximum deflection of tibia varies, the directions of the principal central axis of seven sections of widely different shapes were examined. The direction of one of the principal central axes lies in the plane for maximum deflection of the tibia. By means of the integrator the principal moment of inertia and the positions of the principal central axes were determined. The greatest value of the required angle was  $9.3^\circ$ , which implies an increase of 2.2 per cent in the corresponding moment of inertia from the minimum moment. The results from the other sections are given in table 7. The highest value for the ratio  $I_{max}/I_{min}$  was 2.6.

According to the determinations performed on autopsy specimens, the principal central axes in different sections are practically parallel (Fig. 3), and the tibia would thus not itself produce a rotation while being bent.

TABLE 7 Angle  $\beta$  between chosen plane of bending for the instrument and the bending plane for the minimum moment of inertia. Increase in the moment of inertia corresponding to observed angle  $\beta$ . Ratio  $I_{\max}/I_{\min}$

Subject	1	2	3	5	13	14	18
Angle $\beta$ between chosen and principal central axis; degrees	7.3	-0.5	1.5	9.3	7.8	-1.5	<0.1
$\beta\beta-I_{\min}$ as a percentage of $I_{\min}$	1.4	<0.1	<0.1	2.2	0.5	0.2	<0.1
$I_{\max}/I_{\min}$	1.85	1.29	1.54	1.96	1.28	2.56	1.79

The deflection curve of a particular tibia is unique. As pointed out on page 15, this curve is dependent on the variation of the minimum moment of inertia for the section along the length of tibia. If the weakest section were to be located at the level of the middle pin, this would be the site of the greatest possible deflection of the tibia.

As the centre of torsion and the centroid of the tibia section do not coincide, the deflection of the tibia will be combined with a rotation. The calculations show that in the least favourable case the error in the recorded deflection due to this rotation does not amount to more than +2 per cent.

#### *Factors governing the moment of inertia*

The moment of inertia is difficult to measure in spongy bone, but the narrowest part of the tibia contains only a small amount of such substance. It is difficult to draw a boundary between the cortical and the spongy bone, and the border has been chosen where the cavities of the spongy bone merge with the marrow space. Proximally and distally of the narrowest part of the tibia the spongy bone occupies an increasingly large proportion of the section, and it is difficult to judge its share of the moment of inertia. For other than the narrowest part, it is thus mainly the moment of inertia of the cortical bone that was determined. This means that the value for the sections with a greater proportion of spongy bone is on the low side.

Compact bone varies in porosity and there are divergent opinions on the effect of this structural factor on the physical properties of the bone (Evans, 1958; Smith & Walsmsley, 1958; Currey, 1959; Vose, 1961; Sedlin & Hirsch, 1966; Blaimont, 1968; Evans & Bang, 1968). The fact that the subjects from which the bone specimens were obtained were not above 44 years of age would seem to rule out the possibility of osteoporosis and the specimens probably did not differ essentially in porosity.

The errors in the determination of the deflection and the moment of inertia will evidently affect the observed modulus of elasticity. A large error is due to the constant in eqn. [9]. An accurate determination of the modulus of elasticity would need a specific constant for each bone because of the individual structure of the tibia. It was to some extent surprising that there was not a greater difference in the constant for the five specimens for which it was calculated (standard deviation 5 per cent). With the mean of  $1/67$  for the constant obtained for the pin distance 24 cm, the mean for  $E_{24}$  was  $1.85 \times 10^3$  kgf/mm<sup>2</sup>; for the pin distance of 21 cm and the constant  $1/66$ , the mean for  $E_{21}$  was  $1.75 \times 10^3$  kgf/mm<sup>2</sup>. The corresponding values for the relative experimental error were  $\pm 8$  and  $\pm 9$  per cent for a single measurement.

## *VI. Clinical application*

### MATERIAL

It was originally intended to record the development of stability in all cases of new fractures of the tibial shaft referred to this hospital, but it was soon found that some such fractures displayed good stability after as little as 6—8 weeks of immobilization and there were therefore no therapeutic grounds for performing measurements. Still less was it justified to shorten the first period of immobilization before the fracture had become stable merely to obtain values for the investigation. On the other hand, there were patients in whom healing was slow and did not occur in the usual time, where, to judge from the radiographs, the formation of callus was unsatisfactory or where there was delayed union or risk of pseudarthrosis. It is for such cases that the method was intended as an aid in the evaluation of the healing and the progress of the treatment. The first measurement of the stability of the fractured tibia was therefore not performed until a period had elapsed after the fracture; this ranged from 6 to 39 weeks, with an average of 19. Because of the risk of infection when the pins were inserted, no examination was made in the case of infected leg wounds. When the fracture was located in the extreme distal or proximal part of the tibia, so that the pins had to be inserted quite near the respective joints, no examination could be made because the malleolar and condylar areas afford an unreliable hold.

The material for the study comprised 40 patients with shaft fractures of the tibia, 3 of them with pseudarthroses. Measurements on the tibia of the sound leg of a patient with a trimalleolar fracture were included. Examinations were repeated on two or more occasions in 29 of the patients.

The mean age of the 26 men was  $38 \pm 16$  years (range 17—66) and of the 14 women  $48 \pm 15$  years (range 18—75). The difference between the means is not statistically significant, but the recorded difference points to the possible existence of different external factors responsible for the fracture in men and women.

The errors in the determination of the deflection and the moment of inertia will evidently affect the observed modulus of elasticity. A large error is due to the constant in eqn. [9]. An accurate determination of the modulus of elasticity would need a specific constant for each bone because of the individual structure of the tibia. It was to some extent surprising that there was not a greater difference in the constant for the five specimens for which it was calculated (standard deviation 5 per cent). With the mean of  $1/67$  for the constant obtained for the pin distance 24 cm, the mean for  $E_{24}$  was  $1.85 \times 10^3$  kgf/mm<sup>2</sup>; for the pin distance of 21 cm and the constant  $1/66$ , the mean for  $E_{21}$  was  $1.75 \times 10^3$  kgf/mm<sup>2</sup>. The corresponding values for the relative experimental error were  $\pm 8$  and  $\pm 9$  per cent for a single measurement.

were performed with a pin distance of 21 cm the values were converted to corresponding ones for 24 cm.

The values recorded for the sound tibia are presented in table 8. Where there were two or more values, the variation due to the error of measurement could be separated from the biological variation by means of an analysis of variance. In this case there was an hierarchic classification with case and measurement as sources of variation (Snedecor & Cochran, Chapter 10).

### Results

The male and female patients were assigned to separate groups. The mean observed deflection of the sound tibia was 97  $\mu\text{m}$  for the men and 149  $\mu\text{m}$  for the women. The corresponding relative errors for a single measurement were  $\pm 5$  and  $\pm 9$  per cent.

In the statistical analysis of the results 3 values for each of cases 18, 34, and 41 were omitted (indicated in parentheses in table 8) for the following reasons. For the first measurement on case 18 the middle pin entered obliquely to the side. The middle pin was carefully loosened, but on re-insertion it followed the same track as before. This was reflected in the recorded curve (Fig. 12, curve A), which, as expected, showed a larger deflection than the subsequent ones.

For case 34 the first deflection recorded differed from the subsequent ones owing to the position of the instrument; for a check of the radiographs showed that at the first registration the instrument was 2 cm proximal of its position for the later measurements. The distance of the middle pin from the narrowest part of the tibia for the first registration was 53 mm and for the four subsequent ones 31, 31, 34 and 30 mm. The large difference may be due to the long interval of 24 weeks between the first and second examinations.

Case 41 was an early one in the investigation, when no radiographs were taken with pin in place. In the first measurement the distal pin was located too far distally on the fractured tibia and the instrument was therefore intentionally placed at a more proximal level in the following examinations.

The values of the moment of inertia of the smallest section calculated from eqn. [8],  $I_{\text{min app}} = 0.042 bd^3 - 0.049 a^4$ , are presented in table 9. The model for the statistical analysis is the same as for the analysis of the deflection. The mean moment of inertia for men was 0.94  $\text{cm}^4$  and for women 0.58  $\text{cm}^4$ . The corresponding relative errors for a single measurement were  $\pm 4$  and  $\pm 5$  per cent.

One patient had a two-level fracture, the middle fragment being about 15 cm long. In 5 patients the shaft fracture was located proximally and in the other 34, distally. Seven were open fractures. In 4 cases osteosynthesis had been performed prior to the first measurement and 5 patients underwent a total of 7 operations after this measurement.

The first measurement of the deflection of the tibia was made on average 19 weeks (6—39) after the fracture or the most recent operation. Three patients with pseudarthroses were not included because the treatment had once been regarded as completed. The mean interval between the measurements was 8 weeks (range 3—24); the average was raised considerably by the long time often left between the last two measurements.

Because, at the beginning of this investigation the formula for the moment of inertia of the tibia (eqn. [8]) had not been calculated, the radiographic examination included no films taken with projections enabling the moment of inertia of the bone to be measured. For this reason the moment was not determined for all the stability examinations. So as not to increase the risk of infection, no pin that had loosened and passed out through the skin was re-inserted in the bone.

In some cases a pin loosened when the load was less than 5 kgf, and then the value was extrapolated to 5 kgf so as to enable a comparison to be made with those obtained in subsequent measurements. As the load-deflection curves were fairly linear, extrapolation would not appreciably increase the error of measurement. The extrapolated values are marked with an asterisk in the text and curves. All the curves from the measurements performed are presented.

### MEASUREMENTS ON THE INTACT TIBIA

As the two tibias of any one person displayed close similarities and had practically the same flexural rigidity ( $EI$ ), it is possible from the deflection and moment of inertia of the sound tibia to obtain an impression of the flexural rigidity of the other bone before the fracture. The relation between the observed deflections of the fractured and sound tibias affords a criterion of the stability of the fracture during the course of healing. By repeating the determinations of both deflection and moment of inertia the reproducibility of the clinical measurements could be ascertained. At the same time these values indicate the suitability of the method for determining the modulus of elasticity *intra vitam*.

The reported values relate to the deflection for a pin distance of 24 cm and a load of 5 kgf. In the case of two patients in whom measurements

tion (Snedecor & Cochran, Chapter 12). There was no significant difference between the right and left sides. The estimated relative error for a single measurement was  $\pm 5$  per cent. With the constant  $1/67$ ,  $E$  was obtained as  $2.0 \times 10^3$  kgf/mm<sup>2</sup>.

### Discussion

Measurements on the tibia *intra vitam* differ in a number of respects from those on autopsy specimens. There are several factors that can have a bearing on the magnitude of the deflection.

The living tibia is exposed to the mechanical effects of the surrounding tissues, has a higher water content and is perfused with blood, which is under pressure. The effect of these factors, together with the temperature, burdens the relative errors for the single measurements of the deflection and the moment of inertia.

The deflection is influenced by the temperature, it being greater for the warmer tibia than for the autopsy specimens. In a study of the modulus of elasticity of bone in bending Sedlin (1965) found a 6 per cent lower value at 37 than at 21°C; the difference was statistically significant. This result is consistent with those reported by Smith & Walsley (1959), who found that the elasticity modulus is inversely related to the temperature of the bone specimen.

Unlike the specimen the vital tibia has a constant water content. It has been reported that a short period of exposure of a bone specimen to a room atmosphere is enough to increase the modulus of elasticity of bone; Smith & Walsley (1959) recorded an increase of 7 per cent after one hour; however, for a period of 10 minutes Sedlin (1965) found no change.

The presence of an intact fibula has an effect on the deflection of the tibia. This was tested as follows: The deflection of the tibia on autopsy specimens was registered with the instrument. With this still in place the fibula was sawn off at the level of the middle pin. The values of the deflec-

### *The modulus of elasticity of the sound tibia*

From the means of the observed deflection and moment of inertia the apparent modulus of elasticity for the men and women were calculated, namely  $2.65 \times 10^3$  and  $2.3 \times 10^3$  kgf/mm<sup>2</sup>, respectively; with the constant 1/67 the corresponding values of  $E$  are  $1.9 \times 10^3$  and  $1.6 \times 10^3$  kgf/mm<sup>2</sup>.

The determined error in the observed deflection is the same in the corrected deflection after subtraction of the systematic error of the method. When the relative error of the corrected deflection was calculated and since the relative error in the moment of inertia was known, the relative error of the modulus of elasticity was obtained from the square root of the sum of the squares of the relative errors in the measurement of the deflection and the moment of inertia; it was  $\pm 9$  and  $\pm 12$  per cent for men and women, respectively.

### *The modulus of elasticity of the tibia in controls*

When one tibia is fractured the other one cannot be regarded as completely normal, but may be expected to display changes such as a measure of osteoporosis. It was accordingly considered of interest to perform measurements on normal tibias *intra vitam*. The apparent modulus of elasticity was determined on both tibias in 9 voluntary subjects in sound health and with no history of leg injury. Their mean age was 25 years (range 22–31). The values of the apparent modulus of elasticity (" $E$ ") and the corresponding analysis of variance are given in table 10. The observed values constitute a 2-factor experiment with the subject and the side as sources of varia-

## CLINICAL INVESTIGATION

In this section the patients on whom the stability measurements were performed are presented. The relevant data constitute the basis for the evaluation of the principle and the method for assessing the stability of healing fracture of the tibia.

The values for the deflection of the fractured tibia were examined as regards their correlation with time and the clinical findings and results.

Measurements on the fractured tibia were not performed until the callus had become resilient. Only in the first case (no. 25) were registrations performed while the fracture were quite unstable. The information yielded by the recorded curves was of little value for two reasons: firstly, the clinical findings relating to the stability were reliable and, secondly, the load-deflection curve is easily influenced by the weight of the very mobile fracture fragments which loads the force transducer.

The deflections recorded for a load of 5 kgf on the fractured tibia,  $v_{tot}$ , and the intact tibia,  $v_i$ , at various intervals after fracture are presented in table 12 (page 73), together with the calculated quotient  $s/E_f$  or  $s/E_i/l_f$ . The deflections of both tibias are also presented in graphs with the following case reports.

### Case reports

**CASE 1 L.H.** Bricklayer, 20 years; upper half of the tibia fractured in a road accident. Long leg cast for 22 weeks at another hospital; during last few weeks partial weight bearing, one crutch. *Twenty-two weeks*—Responsible surgeon doubtful whether cast might be removed; fracture nearly stable. Radiographs showed distinct callus but fracture line clearly visible. Deflection 0.172 mm,  $s/E_f=0.44$ . No cast, gradual weight bearing recommended. *Twenty-eight weeks*—Had used a crutch outdoors but full weight bearing indoors. Fracture clinically stable; deflection 0.138 mm,  $s/E_f=0.23$ . *Thirty-four weeks*.—Full weight bearing also outdoors. Deflection 0.128 mm,  $s/E_f=0.18$ . Returned a month later because of occasional falls, but the fractured leg had given no trouble. Radiographs: increased amount of callus, fracture line less clear.

**CASE 2 H.W.** Lorry driver, 25 years; spiral fracture of tibia from falling downstairs. Long leg cast at another hospital. *Eight weeks*.—Fracture clinically unstable. Radiographs: Loose callus; large parts of the fracture line visible. Deflection 0.282 mm;  $s/E_f=0.36$ . Walking boot cast; weight bearing recommended. *Thirteen weeks*.—Fracture clini-

tion after and before resection of the fibula were examined by analysis of variance. They constituted a 2-factor experiment with subject and resection as sources of variation (Snedecor & Cochran, Chapter 12). The analysis showed an almost significant increase in the deflection after resection (Table 11). This increase was on average 2 per cent of the deflection before resection.

If the modulus of elasticity of the sound tibia varies during the course of the investigation, there will be an increase in the error for the reproduced values of deflection. To judge from the observed deflection of the sound tibia, there was no such variation.

The effect on the deflection of varying distance from the middle pin to the narrowest part of the sound tibia was tested on each patient separately. Where there were at least two observations the slope of the regression line was determined by the method of least squares, with the deflection on the axis of  $y$  and the distance of the middle pin from the narrowest part of the tibia on the axis of  $x$ . The regression coefficient was negative in 15 cases and positive in 7 but there was no statistically significant deviation from the horizontal position of the line. The fact that in the measurements an attempt was made to obtain a constant value of  $x$  might explain why the sign test was not significant.

No explanation of the difference in the relative error in the deflection for women and men can be offered, unless it might be ascribed to the greater difficulty in obtaining a firm hold for pins in women over 50 years, possibly because of osteoporosis and a thinner cortical layer.

In the experiments on the autopsy specimens from women it also seemed to be more difficult to fix the pins in the case of the pin distance of 24 cm. This may have been due to the tendency for the tibia to be shorter in the women than the men, with respective averages of 34 and 38 cm. Thus, a pin distance of 21 cm would presumably be more suitable for measurements on the female tibia.

It is obviously more difficult to determine the midline on the medial surface of the tibia *intra vitam*, but otherwise the experimental conditions, with the mentioned exceptions, were much the same as for the autopsy specimen; the views concerning measurements on the specimens presented in the *Discussion* also apply to the tibia *intra vitam*.

The reproducibility of the approximate moment of inertia was acceptable. It would be difficult to attain a higher accuracy without making the radiologic examination much more time-consuming, but, as said before (page 15), a determination of the moment on some more levels of the tibia would give a more reliable value of the moment of inertia of the tibia.

## CLINICAL INVESTIGATION

In this section the patients on whom the stability measurements were performed are presented. The relevant data constitute the basis for the evaluation of the principle and the method for assessing the stability of healing fracture of the tibia.

The values for the deflection of the fractured tibia were examined as regards their correlation with time and the clinical findings and results.

Measurements on the fractured tibia were not performed until the callus had become resilient. Only in the first case (no. 25) were registrations performed while the fracture were quite unstable. The information yielded by the recorded curves was of little value for two reasons: firstly, the clinical findings relating to the stability were reliable and, secondly, the load-deflection curve is easily influenced by the weight of the very mobile fracture fragments which loads the force transducer.

The deflections recorded for a load of 5 kgf on the fractured tibia,  $v_{tot}$ , and the intact tibia,  $v_n$ , at various intervals after fracture are presented in table 12 (page 73), together with the calculated quotient  $s/E_1$  or  $s/E_1 I_1$ . The deflections of both tibias are also presented in graphs with the following case reports.

### Case reports

**CASE 1 L.H.** Bricklayer, 20 years; upper half of the tibia fractured in a road accident. Long leg cast for 22 weeks at another hospital; during last few weeks partial weight bearing, one crutch. *Twenty-two weeks.*—Responsible surgeon doubtful whether cast might be removed; fracture nearly stable. Radiographs showed distinct callus but fracture line clearly visible. Deflection 0.172 mm,  $s/E_1=0.44$ . No cast, gradual weight bearing recommended. *Twenty-eight weeks*—Had used a crutch outdoors but full weight bearing indoors. Fracture clinically stable; deflection 0.138 mm,  $s/E_1=0.23$ . *Thirty-four weeks.*—Full weight bearing also outdoors. Deflection 0.128 mm,  $s/E_1=0.18$ . Returned a month later because of occasional falls, but the fractured leg had given no trouble. Radiographs: increased amount of callus, fracture line less clear.

**CASE 2 H.W.** Lorry driver, 25 years; spiral fracture of tibia from falling downstairs. Long leg cast at another hospital. *Eight weeks.*—Fracture clinically unstable. Radiographs: Loose callus; large parts of the fracture line visible. Deflection 0.282 mm;  $s/E_1=0.36$ . Walking boot cast; weight bearing recommended. *Thirteen weeks.*—Fracture clini-

tion after and before resection of the fibula were examined by analysis of variance. They constituted a 2-factor experiment with subject and resection as sources of variation (*Snedecor & Cochran*, Chapter 12). The analysis showed an almost significant increase in the deflection after resection (Table 11). This increase was on average 2 per cent of the deflection before resection.

If the modulus of elasticity of the sound tibia varies during the course of the investigation, there will be an increase in the error for the reproduced values of deflection. To judge from the observed deflection of the sound tibia, there was no such variation.

The effect on the deflection of varying distance from the middle pin to the narrowest part of the sound tibia was tested on each patient separately. Where there were at least two observations the slope of the regression line was determined by the method of least squares, with the deflection on the axis of  $y$  and the distance of the middle pin from the narrowest part of the tibia on the axis of  $x$ . The regression coefficient was negative in 15 cases and positive in 7 but there was no statistically significant deviation from the horizontal position of the line. The fact that in the measurements an attempt was made to obtain a constant value of  $x$  might explain why the sign test was not significant.

No explanation of the difference in the relative error in the deflection for women and men can be offered, unless it might be ascribed to the greater difficulty in obtaining a firm hold for pins in women over 50 years, possibly because of osteoporosis and a thinner cortical layer.

In the experiments on the autopsy specimens from women it also seemed to be more difficult to fix the pins in the case of the pin distance of 24 cm. This may have been due to the tendency for the tibia to be shorter in the women than the men, with respective averages of 34 and 38 cm. Thus, a pin distance of 21 cm would presumably be more suitable for measurements on the female tibia.

It is obviously more difficult to determine the midline on the medial surface of the tibia *intra vitam*, but otherwise the experimental conditions, with the mentioned exceptions, were much the same as for the autopsy specimen; the views concerning measurements on the specimens presented in the *Discussion* also apply to the tibia *intra vitam*.

The reproducibility of the approximate moment of inertia was acceptable. It would be difficult to attain a higher accuracy without making the radiologic examination much more time-consuming, but, as said before (page 15), a determination of the moment on some more levels of the tibia would give a more reliable value of the moment of inertia of the tibia.

Radiographs: increased callus. Unwilling to return to strenuous work. *Thirty-nine weeks.*—Deflection 0.095 mm,  $s/E_f=0.02$  mm. Referred for occupational therapy.

CASE 4 L.B. Stores supervisor, 58 years; spiral fracture of tibia through fall in snow. Long leg cast. *Thirty-nine weeks.*—Fracture almost stable. Radiographs: incipient callus. Deflection 0.308 mm,  $s/E_f=0.29$ . Long walking boot cast, gradual weight bearing advised. *Forty-eight weeks.*—Fracture loaded in the cast without trouble. Radiographs: incipient consolidation, but large parts of the fracture line still visualized. Fracture clinically almost stable. Deflection 0.192 mm,  $s/E_f=0.14$ . Cast not removed and increased weight bearing, one crutch. *Fifty-five weeks.*—Fracture clinically stable. Radiographic appearances unchanged. Deflection 0.140 mm,  $s/E_f=0.08$ . Cast removed, gradual weight bearing. *Sixty-four weeks.*—Full weight bearing, union regarded as complete. Deflection 0.119 mm,  $s/E_f=0.06$ . *Seventy-four weeks.*—Deflection 0.106 mm,  $s/E_f=0.04$  mm. *Eighty-six weeks.*—Deflection 0.116 mm,  $s/E_f=0.05$ . Returned to work.

CASE 5 K.F. Clerk, 22 years; transverse fracture of upper third of tibia caused by a kick received during football. Long leg cast. *Six weeks.*—Clinically unstable. Radiographs: very loose incipient callus. Deflection 0.882 mm,  $s/E_f=2.04$ . *Eleven weeks.*—Fracture unstable. Radiographs: callus forming a bridge in front, but at back loose. Deflection

cally stable. Radiographs: increasing callus. Deflection 0.217 mm,  $s/E_f=0.19$ . Walking boot cast continued, increased weight bearing advised. *Seventeen weeks.*—Deflection 0.190 mm,  $s/E_f=0.15$ . Full weight bearing continued, no cast. Fracture regarded as united, fulltime work resumed a few weeks later.

**CASE 3 S.S.** General labourer, 53 years; proximal and distal fractures of tibia with 14 cm long middle fragment, result of road accident (Fig. 14). Long leg cast. *Seventeen weeks.*—Two crutches; slight tenderness over the distal fracture. Fracture almost stable; deflection 0.249 mm,  $s/E_f=0.27$ , calculated only for lower fracture, upper one regarded as stable. Walking boot cast, two crutches, gradual weight bearing advised. *Twenty-one weeks.*—Because of pain no increased weight bearing. Radiographs: increasing callus. Deflection 0.193 mm,  $s/E_f=0.18$ . Walking boot cast, one crutch. *Twenty-seven weeks.*—Deflection 0.118 mm,  $s/E_f=0.06$ . *Thirty-one weeks.*—Had used two crutches, but occasionally full bearing. Deflection 0.098 mm,  $s/E_f=0.02$ . Union regarded as complete.

FIGURE 14 Radiographs of fractured tibia taken 17—39 weeks after the fracture. Case 3 S.S.

Radiographs: increased callus. Unwilling to return to strenuous work. *Thirty-nine weeks.*—Deflection 0.095 mm,  $s/E_f=0.02$  mm. Referred for occupational therapy.

CASE 4 L.B. Stores supervisor, 58 years; spiral fracture of tibia through fall in snow. Long leg cast. *Thirty-nine weeks.*—Fracture almost stable. Radiographs: incipient callus. Deflection 0.308 mm,  $s/E_f=0.29$ . Long walking boot cast, gradual weight bearing advised. *Forty-eight weeks.*—Fracture loaded in the cast without trouble. Radiographs: incipient consolidation, but large parts of the fracture line still visualized. Fracture clinically almost stable. Deflection 0.192 mm,  $s/E_f=0.14$ . Cast not removed and increased weight bearing, one crutch. *Fifty-five weeks.*—Fracture clinically stable. Radiographic appearances unchanged. Deflection 0.140 mm,  $s/E_f=0.08$ . Cast removed, gradual weight bearing. *Sixty-four weeks.*—Full weight bearing, union regarded as complete. Deflection 0.119 mm,  $s/E_f=0.06$ . *Seventy-four weeks.*—Deflection 0.106 mm,  $s/E_f=0.04$  mm. *Eighty-six weeks.*—Deflection 0.116 mm,  $s/E_f=0.05$ . Returned to work.

CASE 5 K.F. Clerk, 22 years; transverse fracture of upper third of tibia caused by a kick received during football. Long leg cast. *Six weeks.*—Clinically unstable. Radiographs: very loose incipient callus. Deflection 0.882 mm,  $s/E_f=2.04$ . *Eleven weeks.*—Fracture unstable. Radiographs: callus forming a bridge in front, but at back loose. Deflection

0.450 mm,  $s/E_f=0.94$ . Long walking boot cast, gradual weight bearing advised. *Sixteen weeks*.—Fracture almost stable. Radiographs: increased callus, but fracture line distinctly visualized. Deflection 0.278 mm,  $s/E_f=0.50$ . Two crutches without the cast; gradual weight bearing advised. *Twenty weeks*.—Fracture clinically stable. Radiographs: unchanged callus. Deflection by extrapolation  $0.170^+$  mm,  $s/E_f=0.22$ . One crutch recommended. *Twenty-six weeks*.—Patient had used one crutch outdoors and full weight bearing indoors. Radiographs: unchanged callus. Deflection 0.148 mm,  $s/E_f=0.17$ . Fracture considered to be united; returned to work 6 weeks later. *Forty-one weeks*.—Radiographs showed increased callus. No complaints. Deflection 0.129 mm,  $s/E_f=0.13$ .

CASE 6 L.L. Stores supervisor, 43 years; short oblique fracture of tibia from road accident. Long leg cast. Repeated radiographic examinations had shown no increase in callus. Patient referred to this hospital for operation to hasten healing. *Thirty-eight weeks*.—Fracture clinically almost stable. Radiographs: callus laterally via an intermediate fragment. Deflection 0.209 mm,  $s/E_f=0.21$ . Decided to await result of further examination before deciding on operation to accelerate union. Cast removed; two crutches increasing weight bearing. *Forty-four weeks*.—Had walked up to 1 km a day with one crutch. Fracture clinically stable. Radiographs:

evident callus on the lateral aspect, almost none medially, large parts of the fracture line visualized. Deflection 0.150 mm,  $s/E_f=0.08$ . *Fifty weeks.*—After full weight bearing, no trouble. Radiographs: unchanged callus. Deflection 0.147 mm,  $s/E_f=0.08$ . Full-time work resumed after 6 weeks. *Sixty-three weeks.*—Deflection 0.143 mm,  $s/E_f=0.07$ .

**CASE 7 F.S.** Student, 20 years; open transverse fracture of tibia due to an explosion. Extension treatment 4 weeks; long leg cast 12 weeks. Walking with two crutches but no weight on leg. Because of slow union, attending surgeon at another hospital proposed operation to hasten healing. *Twenty-two weeks.*—Fracture clinically unstable. Radiographs: callus bridge on lateral and posterior aspects; callus less marked on anterolateral aspect but no sclerotic change in fragment ends as in pseudarthrosis. Deflection 0.680 mm,  $s/E_f=0.79$ . Walking boot cast; careful weight bearing advised. *Thirty-one weeks*—Fracture clinically stable. Deflection 0.150 mm,  $s/E_f=0.08$ . No cast, crutches withdrawn. *Forty-nine weeks.*—Full weight bearing. Radiographs: full consolidation. Deflection 0.104 mm,  $s/E_f=0.02$ .

0.450 mm,  $s/E_f=0.94$ . Long walking boot cast, gradual weight bearing advised. *Sixteen weeks.*—Fracture almost stable. Radiographs: increased callus, but fracture line distinctly visualized. Deflection 0.278 mm,  $s/E_f=0.50$ . Two crutches without the cast; gradual weight bearing advised. *Twenty weeks.*—Fracture clinically stable. Radiographs: unchanged callus. Deflection by extrapolation 0.170 mm,  $s/E_f=0.22$ . One crutch recommended. *Twenty-six weeks.*—Patient had used one crutch outdoors and full weight bearing indoors. Radiographs: unchanged callus. Deflection 0.148 mm,  $s/E_f=0.17$ . Fracture considered to be united; returned to work 6 weeks later. *Forty-one weeks.*—Radiographs showed increased callus. No complaints. Deflection 0.129 mm,  $s/E_f=0.13$ .

**CASE 6 L.L.** Stores supervisor, 43 years; short oblique fracture of tibia from road accident. Long leg cast. Repeated radiographic examinations had shown no increase in callus. Patient referred to this hospital for operation to hasten healing. *Thirty-eight weeks.*—Fracture clinically almost stable. Radiographs: callus laterally via an intermediate fragment. Deflection 0.209 mm,  $s/E_f=0.21$ . Decided to await result of further examination before deciding on operation to accelerate union. Cast removed; two crutches increasing weight bearing. *Forty-four weeks.*—Had walked up to 1 km a day with one crutch. Fracture clinically stable. Radiographs:

lent callus on the lateral aspect, almost none medially, large parts of fracture line visualized. Deflection 0.150 mm,  $s/E_f=0.08$ . *Fifty weeks.* After full weight bearing, no trouble. Radiographs: unchanged callus. Deflection 0.147 mm,  $s/E_f=0.08$ . Full-time work resumed after 6 weeks. *Forty-three weeks.*—Deflection 0.143 mm,  $s/E_f=0.07$ .

CASE 7 F.S. Student, 20 years; open transverse fracture of tibia due to an explosion. Extension treatment 4 weeks; long leg cast 4 weeks. Walking with two crutches but no weight on leg. Because of slow union, attending surgeon at another hospital proposed operation to hasten healing. *Twenty-two weeks.*—Fracture clinically unstable. Radiographs: callus bridge on lateral and posterior aspects; callus less marked anterolateral aspect but no sclerotic change in fragment ends as in pseudarthrosis. Deflection 0.680 mm,  $s/E_f=0.79$ . Walking boot cast; careful weight bearing advised. *Thirty-one weeks.*—Fracture clinically stable. Deflection 0.150 mm,  $s/E_f=0.08$ . No cast, crutches withdrawn. *Forty-nine weeks.*—Full weight bearing. Radiographs: full consolidation. Deflection 0.104 mm,  $s/E_f=0.02$ .

0.450 mm,  $s/E_f=0.94$ . Long walking boot cast, gradual weight bearing advised. *Sixteen weeks*.—Fracture almost stable. Radiographs: increased callus, but fracture line distinctly visualized. Deflection 0.278 mm,  $s/E_f=0.50$ . Two crutches without the cast; gradual weight bearing advised. *Twenty weeks*.—Fracture clinically stable. Radiographs: unchanged callus. Deflection by extrapolation 0.170<sup>2</sup> mm,  $s/E_f=0.22$ . One crutch recommended. *Twenty-six weeks*.—Patient had used one crutch outdoors and full weight bearing indoors. Radiographs: unchanged callus. Deflection 0.148 mm,  $s/E_f=0.17$ . Fracture considered to be united; returned to work 6 weeks later. *Forty-one weeks*.—Radiographs showed increased callus. No complaints. Deflection 0.129 mm,  $s/E_f=0.13$ .

**CASE 6 L.L.** Stores supervisor, 43 years; short oblique fracture of tibia from road accident. Long leg cast. Repeated radiographic examinations had shown no increase in callus. Patient referred to this hospital for operation to hasten healing. *Thirty-eight weeks*.—Fracture clinically almost stable. Radiographs: callus laterally via an intermediate fragment. Deflection 0.209 mm,  $s/E_f=0.21$ . Decided to await result of further examination before deciding on operation to accelerate union. Cast removed; two crutches increasing weight bearing. *Forty-four weeks*.—Had walked up to 1 km a day with one crutch. Fracture clinically stable. Radiographs:

CASE 10 G.S. Driver, 53 years; open fracture of tibia. Long leg cast.

*Six weeks.*—Clinically unstable. Radiographs: no visible callus. Deflection 0.510 mm,  $s/E_f=1.13$ . New cast. *Ten weeks.*—Clinically almost stable. Radiographs: incipient callus. Deflection 0.290 mm,  $s/E_f=0.85$ . Walking boot cast. Partial weight bearing. *Sixteen weeks.*—Fracture clinically stable. Radiographs: increased callus. Deflection 0.120 mm,  $s/E_f=0.18$ . *Twenty weeks.*—Radiographs: unchanged callus. Deflection 0.113 mm,  $s/E_f=0.15$ . No cast, gradual weight bearing, two crutches for 4 weeks, then one crutch. *Twenty-nine weeks.*—Full weight bearing. Radiographs: increasing consolidation. Deflection 0.106 mm,  $s/E_f=0.11$ . Full-time work resumed 2 weeks later.

CASE 11 G.C. Engineer, 26 years; fractured tibia during skiing. Cast, delayed union. Eleven months.—Operation at another hospital, unsuccessful; twenty months new operation, sliding inlay graft; long leg cast for 7 months. Partial weight bearing with cast. Radiographs:

CASE 8 N.S. Student, 17 years; open distal fracture of tibia from falling tree. Fracture transfixed by two screws; long leg cast; eleven weeks later short leg cast. *Seventeen weeks.*—Fracture clinically stable. Radiographs: incipient bridging by loose callus. Deflection 0.246 mm,  $s/E_I I_f = 0.13$ . Increased weight bearing advised. *Twenty-two weeks.*—Radiographs: increase in callus. Deflection 0.180 mm,  $s/E_I I_f = 0.06$ . No cast, increased weight bearing; after 3 weeks, one crutch. *Thirty weeks.*—Full weight bearing. Radiographs: increasing callus. Deflection 0.130 mm,  $s/E_I I_f = 0.01$ . *Forty weeks.*—Patient fully active. Radiographs: full consolidation. Deflection 0.99 mm,  $s/E_I I_f < 0$ .

CASE 9 G.W. Student, 21 years; tibia fractured distally during vacation work. Fixation with medullary Küntscher nail, removed one month later because of proximal slipping. Long leg cast. *Eighteen weeks.*—Fracture clinically unstable. Radiographs: minimal, loose callus. Deflection 0.560 mm,  $s/E_I I_f = 1.10$ . New cast. *Twenty-two weeks.*—fracture clinically stable. Radiographs: increased callus, but much of the fracture gap visualized. Deflection 0.305 mm,  $s/E_I I_f = 0.53$ . No cast, gradual weight bearing; two crutches advised. *Twenty-seven weeks.*—Further stabilization. Radiographs: increased bridging callus, but fracture line still visible. Deflection 0.212 mm,  $s/E_I I_f = 0.24$ . Increased weight bearing with only one crutch a week or two, then full weight bearing. *Thirty weeks.*—Deflection 0.160 mm,  $s/E_I I_f = 0.12$ . *Thirty-nine weeks.*—Walks, full weight bearing, no trouble. Radiographs: increased callus, bridging on the lateral aspect. Deflection 0.125 mm,  $s/E_I I_f = 0.03$ . Fracture regarded as united.

FIGURE 15 Radiographs of fractured tibia taken 34–84 weeks after fracture Case 12 LP

fracture of graft. Attending surgeon discussed further operation. *Thirty-two weeks* after latest operation.—Fracture unstable. Deflection 0.500 mm,  $s/E_f=0.36$ . Two crutches gradual weight bearing. *Forty-one weeks*.—For some weeks, one crutch. Radiographs: no change in callus. Fracture unstable. Deflection 0.430 mm,  $s/E_f=0.29$ . Continued with one crutch for a month, then full weight bearing. *Fifty-seven weeks*.—Fracture clinically stable. Radiographs: slight increase of callus. Deflection 0.218 mm,  $s/E_f=0.13$ . After a month work resumed. No residual symptoms. *Seventy weeks*.—Deflection 0.162 mm,  $s/E_f=0.06$ .

CASE 12 L.P. Carpenter, 44 years; fracture of proximal half of tibia in road accident. Extension, transfixed long leg cast. Sound tibia measured after *one week*.—Deflection 0.075 mm. *Ten weeks*.—Cast renewed. Fracture too unstable for measurement. Sound tibia, deflection 0.070 mm. *Thirteen weeks*.—Likewise; fracture unstable. Radiographs: large fracture gap. Sound tibia, deflection 0.084 mm. Operation to hasten union considered, but patient preferred to continue with cast. Eight months after fracture, instability persisted but careful loading of leg in a long leg cast permitted. *Thirty-four weeks*.—Fracture unstable. Radiographs: slight increase of callus from negligible (Fig. 15). Deflection 0.880 mm,  $s/E_f=1.75$ . Long walking boot cast, gradual weight bearing continued. *Forty-one weeks*.—Clinically unstable. Radiographs: no change. Deflection 0.530 mm,  $s/E_f=0.96$ . New cast. *Forty-seven weeks*.—Clinically unstable. Radiographs unchanged. Deflection 0.392 mm,  $s/E_f=0.67$ . Because the middle pin loosened, radiographs were taken without pins in place. Considerable stiffness in the knee and ankle owing to the long period of immobilization; cast removed. Two crutches; instructed to put weight on leg carefully; despite this warning, had sometimes put full weight on the leg though without pain or aching. *Fifty-three weeks*.—Fracture unstable. Radiographs: unchanged callus. Deflection 0.493 mm,  $s/E_f=0.88$ . Because of this increase and to prevent development of pseudarthrosis, use of knee cast. Partial weight bearing permitted, but with two crutches. *Sixty weeks*.—Fracture unstable. Deflection 0.250 mm,  $s/E_f=0.35$ . Knee cast continued, increased weight bearing. *Sixty-nine weeks*.—Occasional full weight bearing, no pain. Fracture clinically stable. Radiographs: increase in callus. Deflection 0.226 mm,  $s/E_f=0.30$ . Cast removed, one crutch withdrawn two weeks before last measurement. *Eighty-four weeks*.—Knee mobility 180—80°, ankle 75—135°. Circumference of the thigh 1 cm less on side of fracture. Deflection 0.127 mm,  $s/E_f=0.07$ . One month later full-time work resumed. Union complete; no residual disability.

tibia, deflection 0.086 mm. *Fourteen weeks.*—Fracture still quite unstable. Radiographs: no evidence of consolidation (Fig. 16); corresponding original load-deflection curves representing course of healing in figure 17. Deflection 1.210 mm,  $s/E_I=1.55$ . *Twenty-one weeks.*—No change; deflection 1.200 mm,  $s/E_I=1.57$ . *Twenty-five weeks.*—Fracture unstable. Radio-

Note that in the curves 14 and 21 weeks after fracture the scale for deflection is different from that for the other curves

graphs unchanged. Deflection 0.718 mm,  $s/E_f=0.90$ . Long walking boot cast. Gradual weight bearing. *Thirty-four weeks*.—Fracture unstable. Radiographs: slight callus on anterior aspect. Deflection 0.446 mm,  $s/E_f=0.49$ . Patellar-tendon-bearing (PTB) cast; two crutches and gradual weight bearing. *Thirty-eight weeks*.—Clinically almost stable. Deflection 0.376 mm,  $s/E_f=0.41$ . Continued PTB cast, increased weight bearing. *Forty-five weeks*.—One crutch, occasionally full weight bearing; fracture stable. Radiographs: increase in callus. Deflection 0.222 mm,  $s/E_f=0.19$ . Increased weight bearing without cast advised. *Fifty-two weeks*.—A year after accident, full weight bearing, slight limp because of pain in the ankle. Knee mobility 180—90° ankle 85—120°. Deflection 0.149 mm,  $s/E_f=0.08$ . Fracture considered united. Radiographs showed consolidation.

CASE 14 S.G. Building worker, 47 years; fractured tibia in a fall in street. Transfixion and long leg cast. *Fifteen weeks*.—Fracture unstable. Radiographs: no callus. Deflection 0.243 mm,  $s/E_f=0.41$ . PTB cast, partial weight bearing. *Twenty-one weeks*.—Fracture almost stable, clinically. Radiographs: no definite bridging by callus; fracture line clearly visible. Deflection 0.222 mm,  $s/E_f=0.26$ . Tenderness around fracture. Cast retained. *Twenty-seven weeks*.—Clinically stable. Radiographs: fracture line still evident, but callus increased. Deflection 0.110 mm,  $s/E_f=0.06$ . No cast; gradual weight bearing, at first two crutches. *Thirty-two weeks*.—Fracture regarded as clinically healed. Radiographs: increase of callus, but much of fracture line visualized. Deflection 0.100 mm,  $s/E_f=0.02$ .

CASE 15 N.G. Draughtsman, 20 years; fractured tibia during skiing. Long leg cast. *Eight weeks*.—Clinically unstable. Radiographs: loose callus. Deflection 1.120 mm,  $s/E_f=1.92$ . PTB cast; two crutches. *Fifteen weeks*.—Fracture unstable. Radiographs: increase of callus. Deflection 0.540 mm,  $s/E_f=0.73$ . *Twenty weeks*.—Weight bearing gradu-

ally increased, occasional full weight bearing for a few steps. Fracture almost stable clinically. Deflection 0.278 mm,  $s/E_f=0.25$ . Exercise mobility; first with two crutches, later one, without cast. *Twenty-four weeks.*—Last seven days, full weight bearing. Walks of up to 90 min. Fracture regarded as healed. Deflection 0.186 mm,  $s/E_f=0.10$ . *Thirty-eight weeks.*—No residual symptoms. Deflection 0.139 mm,  $s/E_f=0.02$ .

CASE 16 A.D. Typographer, 35 years; fractured tibia in fall. Long leg cast. *Fifteen weeks.*—Clinically unstable. Radiographs: loose callus and clearly visualized fracture gap. Deflection 0.234 mm,  $s/E_f=0.63$ . Same day, open reduction and transfixion of fracture with AO screws and long leg cast. *Twenty-seven weeks.*—Fracture clinically stable. Radiographs: good callus. Deflection 0.136 mm,  $s/E_f=0.18$ . Cast removed; gradual weight bearing. *Thirty-three weeks.*—Full weight bearing; no residual trouble. Radiographs: consolidation. Deflection 0.119 mm,  $s/E_f=0.11$ . Fracture regarded as healed.

graphs unchanged. Deflection 0.718 mm,  $s/E_f=0.90$ . Long walking boot cast. Gradual weight bearing. *Thirty-four weeks*.—Fracture unstable. Radiographs: slight callus on anterior aspect. Deflection 0.446 mm,  $s/E_f=0.49$ . Patellar-tendon-bearing (PTB) cast; two crutches and gradual weight bearing. *Thirty-eight weeks*.—Clinically almost stable. Deflection 0.376 mm,  $s/E_f=0.41$ . Continued PTB cast, increased weight bearing. *Forty-five weeks*.—One crutch, occasionally full weight bearing; fracture stable. Radiographs: increase in callus. Deflection 0.222 mm,  $s/E_f=0.19$ . Increased weight bearing without cast advised. *Fifty-two weeks*.—A year after accident, full weight bearing, slight limp because of pain in the ankle. Knee mobility 180—90° ankle 85—120°. Deflection 0.149 mm,  $s/E_f=0.08$ . Fracture considered united. Radiographs showed consolidation.

CASE 14 S.G. Building worker, 47 years; fractured tibia in a fall in street. Transfixion and long leg cast. *Fifteen weeks*.—Fracture unstable. Radiographs: no callus. Deflection 0.243 mm,  $s/E_f=0.41$ . PTB cast, partial weight bearing. *Twenty-one weeks*.—Fracture almost stable, clinically. Radiographs: no definite bridging by callus; fracture line clearly visible. Deflection 0.222 mm,  $s/E_f=0.26$ . Tenderness around fracture. Cast retained. *Twenty-seven weeks*.—Clinically stable. Radiographs: fracture line still evident, but callus increased. Deflection 0.110 mm,  $s/E_f=0.06$ . No cast; gradual weight bearing, at first two crutches. *Thirty-two weeks*.—Fracture regarded as clinically healed. Radiographs: increase of callus, but much of fracture line visualized. Deflection 0.100 mm,  $s/E_f=0.02$ .

CASE 15 N.G. Draughtsman, 20 years; fractured tibia during skiing. Long leg cast. *Eight weeks*.—Clinically unstable. Radiographs: loose callus. Deflection 1.120 mm,  $s/E_f=1.92$ . PTB cast; two crutches. *Fifteen weeks*.—Fracture unstable. Radiographs: increase of callus. Deflection 0.540 mm,  $s/E_f=0.73$ . *Twenty weeks*.—Weight bearing gradu-

ally increased, occasional full weight bearing for a few steps. Fracture almost stable clinically. Deflection 0.278 mm,  $s/E_f=0.25$ . Exercise mobility; first with two crutches, later one, without cast. *Twenty-four weeks.*—Last seven days, full weight bearing. Walks of up to 90 min. Fracture regarded as healed. Deflection 0.186 mm,  $s/E_f=0.10$ . *Thirty-eight weeks.*—No residual symptoms. Deflection 0.139 mm,  $s/E_f=0.02$ .

CASE 16 A.D. Typographer, 35 years; fractured tibia in fall. Long leg cast. *Fifteen weeks*—Clinically unstable. Radiographs: loose callus and clearly visualized fracture gap. Deflection 0.234 mm,  $s/E_f=0.63$ . Same day, open reduction and transfixion of fracture with AO screws and long leg cast. *Twenty-seven weeks.*—Fracture clinically stable. Radiographs: good callus. Deflection 0.136 mm,  $s/E_f=0.18$ . Cast removed; gradual weight bearing. *Thirty-three weeks.*—Full weight bearing; no residual trouble. Radiographs: consolidation. Deflection 0.119 mm,  $s/E_f=0.11$ . Fracture regarded as healed.

16 A.D

CASE 16 A.D. Typographer, 35 years; fractured tibia in fall. Long leg cast. *Fifteen weeks.*—Clinically unstable. Radiographs: loose callus and clearly visualized fracture gap. Deflection 0.234 mm,  $s/E_f=0.63$ . Same day, open reduction and transfixion of fracture with AO screws and long leg cast. *Twenty-seven weeks.*—Fracture clinically stable. Radiographs: good callus. Deflection 0.136 mm,  $s/E_f=0.18$ . Cast removed; gradual weight bearing. *Thirty-three weeks.*—Full weight bearing; no residual trouble. Radiographs: consolidation. Deflection 0.119 mm,  $s/E_f=0.11$ . Fracture regarded as healed.

CASE 17 R.J. Porter for block of flats, 53 years; fractured skull, ribs and tibia in a road accident. Long leg cast. *Seven weeks.*—Fracture clinically unstable. Radiographs: loose callus. Deflection 0.317 mm,  $s/E_f=0.49$ . PTB cast, partial weight bearing. *Twelve weeks.*—Fracture clinically stable. Radiographs: slow increase of callus, minimal on posterior and lateral aspects. Deflection 0.212 mm,  $s/E_f=0.22$ . *Sixteen weeks.*—Fracture clinically stable. Radiographs: unchanged callus. Deflection 0.154 mm,  $s/E_f=0.09$ . No cast. *Twenty-one weeks.*—Full weight bearing. Radiographs: good callus. Fracture line less distinct. Deflection 0.126 mm,  $s/E_f=0.02$ . Union of fracture complete.

FIGURE 18 Radiographs of fractured tibia taken 28–55 weeks after fracture Case 18 A.B.

CASE 18 A.B. Dock worker, 42 years; fractured tibia in road accident. Long leg cast. Fracture malunited. Varus position, angle more than  $20^{\circ}$ . Six months later, walking without support, persistent symptoms owing to foot deformity. Corrective osteotomy attempted; long leg cast worn. *Twenty-eight weeks* after operation.—Osteotomy unstable. Radiographs: poor callus (Fig. 18). Deflection 0.452 mm,  $s/E_1=0.30$ . PTB cast; gradual weight bearing. *Thirty-three weeks*.—Clinically unstable. Radiographs: unchanged status. Deflection 0.487 mm,  $s/E_1=0.35$ . Continued PTB cast. *Thirty-seven weeks*.—Clinically unstable. Full weight bearing in cast. Deflection 0.522 mm,  $s/E_1=0.34$ . PTB cast continued. *Forty-three weeks*.—Some clinical increase in stability—almost stable. Radiographs: fracture line less distinct. Deflection 0.339 mm,  $s/E_1=0.17$ . No cast. Full weight bearing. At this fourth measurement reduction in deflection first registered *Fifty-five weeks*—Full weight bearing. Fracture unstable. Radiographs: no increase of callus. Deflection 0.370 mm,  $s/E_1=0.23$ . Regarded as a case of delayed healing.

CASE 19 S.K. Office worker, 39 years, amateur footballer. Transverse fracture in the middle of tibia from kick. Long leg cast. Fracture healed well and football training resumed a year later, but a new fracture or refracture occurred. New cast. *Twenty-three weeks*—Attending surgeon doubtful whether to permit full weight bearing. Patient had been walking with crutches for two months without cast. Deflection 0.092 mm,  $s/E_1=0.03$ . Radiographs: bridging good callus. Full weight bearing advised; union regarded as complete.

CASE 20 H.M. Saw-mill worker, 21 years, suspected abuse of narcotics; on jumping from third floor window suffered vertebral compression fracture of  $L_5$ , acetabular and calcaneal fractures and open tibia fracture. This did not heal normally, but valgus position gradually developed, with poor callus. Osteotomy, reduction and immobilization in cast. *Seventeen weeks*—Fracture clinically unstable. Radiographs: poor callus. Deflection 0.583 mm,  $s/E_1=0.40$ . Walking boot cast. *Twenty-seven weeks*—Clinically stable. Full weight bearing, walking without trouble. Unwilling to undergo further examinations.

CASE 21 H.H. Retired head water, 63 years; proximal fracture of tibia resulting from fall. Long leg cast. *Fifteen weeks*.—Clinically almost stable. Radiographs: bridging callus, fracture line still visible. Deflection 0.235 mm,  $s/E_1=0.29$ ; extrapolation from 4 kgf. No cast. Recovery uneventful.

CASE 22 A.C. Shop-keeper, 62 years; proximal fracture of tibia through fall. Long leg cast. *Fourteen weeks*.—Fracture clinically stable. Radiographs: evident callus, but parts of the fracture line clearly visible. Deflection 0.154 mm,  $s/E_1=0.18$ . No cast; gradual weight bearing. *Nineteen weeks*.—Walking without support. Patient considered fracture as healed and refused further examinations. Fracture regarded as united. Returned to half-time work and 6 weeks later to full time. No residual trouble.

CASE 23 L.H. No regular occupation, 28 years, alcoholic; open fracture of tibia in road accident. Below-knee cast and transfixion with Kirschner wires. Skin necrosis and infection. *Ten weeks*.—Sequestroectomy performed. *Fourteen weeks*.—Fracture clinically unstable. Radiographs: poor callus. Deflection 0.221 mm. Long leg walking boot cast. Patient had no trouble with the leg and himself broke away the cast, returned 10 months later because of recurrence of osteitis in fracture. Walked without difficulty since he had removed the cast. Radiographs: united fracture.

CASE 24 B.O. Seaman, 23 years; tibia fractured in accident on board ship. Open reduction and transfixion with an Egger's plate. Returned to work after 6 months. Worked for 3 years, but during military service leg pained on strenuous marches. At site of the four-years-old fracture radiographs disclosed thick callus about twice diameter of tibia shaft. Clinically full stability. Deflection 0.088 mm; sound tibia, 0.054 mm. Attending surgeon preferred operation. Healing normal. Returned to work 4 months later. Since fracture was stable before operation, and especially as the metal plate was left in place, there was no reason to perform further measurements of stability.

CASE 25 I.A. Shop assistant, 38 years; alcoholic; tibia fractured in road accident. Cast; no healing. *Twenty-two weeks*.—Fracture quite unstable. Deflection 2.03 mm; sound tibia 0.093 mm. Osteosynthesis same day with inlay graft and Hoffman fixation. No union. *Thirty-six weeks*.—Fracture quite unstable. Deflection 3.29 mm; sound tibia, 0.086 mm. A week later re-operation, osteosynthesis with screws and on-lay graft. A month later transferred to the hospital of home-town.

CASE 26 E.J. Electrician, 46 years; oblique fracture of tibia in fall. Reduction and long leg cast. *Twenty-two weeks*.—Fracture clinically unstable according to attending surgeon. Radiographs: evi-

dent callus. Deflection 0.119 mm,  $s/E_t=0.05$ . Stability measurements pointed to reliable stability, cast discontinued. Gradual weight bearing permitted. *Twenty-seven weeks.*—Fracture clinically stable; no further measurements; fracture regarded as healed. Returned to full-time work in 3 weeks.

**CASE 27 I.S.** Cashier, 40 years; fracture of tibia. Plaster cast. *Eighteen weeks.*—Clinically almost stable. At the first attempt to measure stability no sure hold for the distal pins obtained. Radiographs: no evidence of callus. Two days later, with different pin positions, deflection 0.280 mm,  $s/E_t=0.28$ . Walking boot cast; gradual weight bearing on cast recommended. *Twenty-five weeks.*—Clinically almost stable. Radiographs: incipient formation of callus. Deflection 0.238 mm,  $s/E_t=0.22$ . Walking boot cast. *Thirty-one weeks.*—Fracture clinically stable. Radiographs: incipient callus. Deflection 0.192 mm,  $s/E_t=0.13$ . Full weight bearing without support. *Thirty-seven weeks.*—Fracture stable. Radiographs: increase of callus. Deflection 0.181 mm,  $s/E_t=0.09$ . Fracture regarded as clinically healed, return to work recommended; five weeks later working full time.

**CASE 28 V.G.** Clerk, 59 years, fracture of tibia. Long leg cast. *Eight weeks.*—Fracture unstable. Radiographs: incipient callus. Deflection 0.524 mm,  $s/E_t=0.86$ . Long leg cast renewed. *Fifteen weeks.*—Fracture almost clinically stable. Deflection 0.410+ mm,  $s/E_t=0.58$ ; extra-

CASE 22 A.C. Shop-keeper, 62 years; proximal fracture of tibia through fall. Long leg cast. *Fourteen weeks*.—Fracture clinically stable. Radiographs: evident callus, but parts of the fracture line clearly visible. Deflection 0.154 mm,  $s/E_f=0.18$ . No cast; gradual weight bearing. *Nineteen weeks*.—Walking without support. Patient considered fracture as healed and refused further examinations. Fracture regarded as united. Returned to half-time work and 6 weeks later to full time. No residual trouble.

CASE 23 L.H. No regular occupation, 28 years, alcoholic; open fracture of tibia in road accident. Below-knee cast and transfixion with Kirschner wires. Skin necrosis and infection. *Ten weeks*.—Sequestroectomy performed. *Fourteen weeks*.—Fracture clinically unstable. Radiographs: poor callus. Deflection 0.221 mm. Long leg walking boot cast. Patient had no trouble with the leg and himself broke away the cast, returned 10 months later because of recurrence of osteitis in fracture. Walked without difficulty since he had removed the cast. Radiographs: united fracture.

CASE 24 B.O. Seaman, 23 years; tibia fractured in accident on board ship. Open reduction and transfixion with an Egger's plate. Returned to work after 6 months. Worked for 3 years, but during military service leg pained on strenuous marches. At site of the four-years-old fracture radiographs disclosed thick callus about twice diameter of tibia shaft. Clinically full stability. Deflection 0.088 mm; sound tibia, 0.054 mm. Attending surgeon preferred operation. Healing normal. Returned to work 4 months later. Since fracture was stable before operation, and especially as the metal plate was left in place, there was no reason to perform further measurements of stability.

CASE 25 I.A. Shop assistant, 38 years; alcoholic; tibia fractured in road accident. Cast; no healing. *Twenty-two weeks*.—Fracture quite unstable. Deflection 2.03 mm; sound tibia 0.093 mm. Osteosynthesis same day with inlay graft and Hoffman fixation. No union. *Thirty-six weeks*.—Fracture quite unstable. Deflection 3.29 mm; sound tibia, 0.086 mm. A week later re-operation, osteosynthesis with screws and on-lay graft. A month later transferred to the hospital of home-town.

CASE 26 E.J. Electrician, 46 years; oblique fracture of tibia in fall. Reduction and long leg cast. *Twenty-two weeks*.—Fracture clinically unstable according to attending surgeon. Radiographs: evi-

$s/E_f=0.03$ . *Forty-eight weeks*.—Deflection 0.153 mm,  $s/E_f=0.01$ . Full weight bearing and walks advised. Three months later patient had loaded the leg fully without trouble and returned to full-time work. Radiographs: consolidation.

CASE 31 K.E. Clerk, 55 years, tibia fractured in road accident. *Thirteen weeks*—Fracture unstable. Radiographs: incipient callus. Deflection 1.290 mm,  $s/E_f=0.54$ . Renewed long leg cast. *Twenty-one weeks*—Fracture almost stable. Radiographs: increase of callus (Fig. 19). Deflection 0.760 mm,  $s/E_f=0.29$ , two crutches, careful loading. *Twenty-seven weeks*—Clinically stable. Deflection 0.720\* mm,  $s/E_f=0.25$ , extrapolation from 4 kgf; one crutch. *Thirty-three weeks*.—Deflection 0.540\* mm,  $s/E_f=0.17$ ; extrapolation from 3.5 kgf. Full weight bearing without support. *Forty weeks*.—Walked without trouble. Fracture regarded as clinically healed. Radiographs: fracture consolidated. Deflection 0.389 mm,  $s/E_f=0.11$ .

FIGURE 19 Radiographs of fractured tibia taken 13–40 weeks after fracture Case 31 K.E.

polation from 3 kgf. Walking boot cast. *Nineteen weeks*.—Fracture unstable. Radiographs: consolidation of the fracture laterally, incipient consolidation medially. Deflection 0.322 mm,  $s/E_f=0.40$ , extrapolation from 3.5 kgf. Cast removed, gradual weight bearing, directed to use two crutches. *Twenty-seven weeks*.—Fracture had then been clinically stable for past month and for two weeks only one crutch had been used. Fracture regarded as healed; no support required. Deflection 0.300 mm,  $s/E_f=0.33$ . Nine weeks later half-time work resumed; no residual deformity. Radiographs showed complete consolidation of shaft fracture.

CASE 29 V.L. Housewife, 36 years; transverse fracture of tibia in road accident. Long leg cast. *Thirty-one weeks*.—Clinically almost stable. Radiographs: no over-riding callus; fracture line visible. Deflection (21-cm pin distance) 0.303 mm,  $s/E_f=0.31$ . Long walking boot cast. *Thirty-six weeks*.—Fracture clinically stable stability measurement unsuccessful—no radiographs to verify distance from middle pin to centre of fracture. *Forty-one weeks*.—Deflection 0.142 mm,  $s/E_f=0.10$ . Cast removed. *Forty-six weeks*.—Fracture stable; full weight bearing. Deflection 0.097 mm,  $s/E_f=0.03$ . *Fifty-one weeks*.—Full weight bearing, clinical union. Radiographs: still no over-riding callus on medial aspect of shaft fracture. Deflection 0.088 mm,  $s/E_f=0.02$ . Recommended resume work half-time. *Seventy-five weeks*.—Recovery complete, working full-time; no disability. Radiographs: complete consolidation. Deflection 0.099 mm,  $s/E_f=0.02$ .

CASE 30 M.N. Housewife, 49 years, open fracture of tibia in road accident. *Twenty-eight weeks*.—Fracture stable for last couple of months. Radiographs: poor callus development. Deflection 0.177 mm,  $s/E_f=0.04$ ; indicative of good stability; cast removed, weight bearing recommended. *Thirty-nine weeks*.—Because mobility reduced in both knee and ankles, patient had still not dared to put weight on the leg without support. Varus position of ankle; no crutches. Deflection 0.166 mm,

almost stable. Deflection 0.610\* mm,  $s/E_f = 0.20$ , extrapolation from 4 kgf, cast discontinued; two crutches. Six weeks later fracture clinically stable. Fifty-nine weeks — Deflection 0.349 mm,  $s/E_f = 0.11$ . Walking without trouble; recovery complete. Radiographs: increasing callus during course of treatment.

CASE 34 K.Å. Housekeeper, 50 years, open tibia fracture. Long leg cast. *Fifteen weeks.* — Fracture unstable. Radiographs: no callus. Deflection 1.220 mm,  $s/E_f = 0.86$ . *Twenty-two weeks.* — Open reduction. Transfixion with AO screw. Long leg cast. *Thirty-nine weeks.* — Fracture unstable. Radiographs: poor callus. Fracture line clearly visible. Deflection 0.745 mm,  $s/E_f = 0.39$ . *Forty-five weeks.* — Clinically unstable. Deflection 0.560\* mm,  $s/E_f = 0.28$ , extrapolation from 4 kgf. PTB cast; gradual weight bearing. *Fifty-two weeks.* — Clinically stable. Radiographs:

CASE 32 U.K. Dentist, 27 years, tibia fracture during skiing. Long leg cast. *Eighteen weeks.*—Fracture clinically stable. Radiographs: incomplete healing. Deflection 0.154 mm,  $s/E_f = 0.03$ , indicative of stability. Cast discontinued, full weight bearing. *Twenty-three weeks.*—Deflection 0.163 mm,  $s/E_f = 0.04$ . Fracture was regarded as healed.

CASE 33 C.S. Clerk, 65 years; tibia fractured in road accident. Long leg cast. *Twenty-seven weeks.*—No union, increasing valgus position. Corrective osteotomy and autologous bone graft. Prior to the operation, deflection 1.240 mm,  $s/E_f = 0.67$ , extrapolation from 4 kgf. *Thirty-eight weeks.*—Eleven weeks after the operation, fracture still unstable. Deflection 1.280 mm,  $s/E_f = 0.56$ , also extrapolated from 4 kgf. Long leg cast; careful loading recommended. *Forty-four weeks.*—Fracture

ration precluded further stability measurement. Radiographs: consolidation of pseudarthrosis.

**CASE 36 K.W.** Housewife, 44 years, tibia fractured during skiing. Long leg cast. *Twenty-nine weeks*.—Fracture clinically stable. Radiographs: incipient consolidation. Deflection 0.265\* mm,  $s/E_1=0.10$ . PTB cast 3 more weeks, full weight bearing without support. *Forty-nine weeks*.—Radiographs: consolidation.

**CASE 37 V.N.** 75 years; fractured femur (intertrochanteric) and tibia on same side in road accident. Long leg cast. *Thirteen weeks*.—Radiographs: bridging callus, mostly on lateral aspect. Cast discontinued. Deflection 0.360\* mm, extrapolation from 3 kgf; sound tibia, 0.200 mm. *Twenty weeks*.—Deflection 0.335 mm. Long walking boot cast because of need to load right leg owing to intertrochanteric fracture. Removed after one week; crutches; gradual weight bearing. Both measurements pointed to good stability. Further course uneventful. *Thirty-six weeks* —Recovered; full weight bearing.

**CASE 38 E.R.** Clerk, 18 years, tibia fractured in road accident. Long leg cast. *Seventeen weeks* —Radiographs: little increase in previously minimal callus. Attending surgeon found stability doubtful. Deflection 0.252 mm,  $s/E_1=0.15$ , sound tibia, 0.137 mm; indicative of stability, cast discontinued, two crutches. *Twenty-two weeks*. —Increased weight bearing. Deflection 0.210 mm,  $s/E_1=0.11$ . *Twenty-eight weeks*. —Fracture clinically healed, full weight bearing.

**CASE 39 A.B.** Housewife, 48 years; tibia fractured in road accident. Treated at another hospital; two year later complained of pain on effort. Radiographs: pseudarthrosis; clinically unstable. Deflection 0.553 mm, sound tibia, 0.096 mm. Pseudarthrosis operation, osteosyn-

good callus. Deflection 0.340 mm,  $s/E_I=0.13$ . *Sixty-one weeks*.—Walking without support; clinically healed. Radiographs: increasing callus, fracture consolidated. Deflection 0.227 mm,  $s/E_I=0.05$ .

**CASE 35 A.L.** Office cleaner, 60 years; open tibia fracture. Open reduction, osteosynthesis with loops of wire. Long leg cast for three months; fracture regarded as healed. *Fifty-two weeks*.—Complained of pain in leg during walks. Fracture clinically stable. Radiographs: pseudarthrosis with marked sclerotic periosteal reaction. Deflection (21-cm pin distance) 0.108 mm; sound tibia, 0.092 mm; indicative of complete stability. During removal of the wires part of protecting callus chipped away, resulting in mobility between sclerotic bone ends, a pseudarthrosis. Autologous bone graft was inserted. Necrosis of wound margins, secretion, fistula. *Seventy-two weeks*.—Fistula still present. Infection in area of ope-

ration precluded further stability measurement. Radiographs: consolidation of pseudarthrosis.

CASE 36 K.W. Housewife, 44 years, tibia fractured during skiing. Long leg cast. *Twenty-nine weeks*.—Fracture clinically stable. Radiographs: incipient consolidation. Deflection 0.265 mm,  $s/E_f=0.10$ . PTB cast 3 more weeks, full weight bearing without support. *Forty-nine weeks*.—Radiographs: consolidation.

CASE 37 V.N. 75 years; fractured femur (intertrochanteric) and tibia on same side in road accident. Long leg cast. *Thirteen weeks*.—Radiographs: bridging callus, mostly on lateral aspect. Cast discontinued. Deflection 0.360 mm, extrapolation from 3 kgf; sound tibia, 0.200 mm. *Twenty weeks*.—Deflection 0.335 mm. Long walking boot cast because of need to load right leg owing to intertrochanteric fracture. Removed after one week; crutches; gradual weight bearing. Both measurements pointed to good stability. Further course uneventful. *Thirty-six weeks*—Recovered; full weight bearing.

CASE 38 E.R. Clerk, 18 years; tibia fractured in road accident. Long leg cast. *Seventeen weeks*—Radiographs: little increase in previously minimal callus. Attending surgeon found stability doubtful. Deflection 0.252 mm,  $s/E_f=0.15$ , sound tibia, 0.137 mm, indicative of stability, cast discontinued; two crutches. *Twenty-two weeks*—Increased weight bearing. Deflection 0.210 mm,  $s/E_f=0.11$ . *Twenty-eight weeks*.—Fracture clinically healed; full weight bearing.

CASE 39 A.B. Housewife, 48 years; tibia fractured in road accident. Treated at another hospital; two year later complained of pain on effort. Radiographs: pseudarthrosis; clinically unstable. Deflection 0.553 mm, sound tibia, 0.096 mm. Pseudarthrosis operation, osteosyn-

thesis with screws and autologous bone graft. Postoperative course uneventful; normal recovery time.

CASE 40 B.H. Nurse, 50 years; tibia fractured in road accident. Reduction, long leg cast. *Thirteen weeks*.—Radiographs: minimal callus. *Sixteen weeks*.—Clinically unstable. Deflection  $0.400^*$  mm,  $s/E_I I_f = 0.55$ ; sound tibia, 0.155 mm. Walking boot cast. Returned to former hospital for further treatment. Recovery uneventful.

CASE 41 M.Z. Clerk, 67 years; trimalleolar fracture. Patient not included in series but values included in analysis of error of determination of deflection of sound tibia and moment of inertia from formula for  $I_{app}$ , because two measurements had been performed on sound tibia and radiographs had been taken in suitable projections. Determinations performed 4 and 6 months after fracture.

### Results

The values of  $s/E_I$  or  $s/E_I I_f$  obtained at the examinations where the clinical evaluation of the stability of the fracture was followed by a new step in treatment or where the fracture was regarded as stable are given in the table 13. Treatment with walking boot cast was given in the interval  $s/E_I = 0.66-0.21$  ( $n=17$ ); removal of the cast and use of two crutches was begun at the value of 0.31 ( $n=12$ ); the fracture was judged to be stable when  $s/E_I = 0.30-0.17$  ( $n=22$ ) and full weight bearing was introduced at  $s/E_I = 0.17-0.10$  ( $n=17$ ).

The healing time for the fracture varied individually and the average time after fracture until full weight bearing was resumed was 33 weeks (range 16-69) for 34 patients.

The stability of the callus is expressed by the ratio  $s/E_I I_f$ , whose values at various intervals after fracture have been entered in figure 20. The slope of the line between two measurements gives the average rate of healing. The advantage of expressing the deflection of the callus by the ratio  $s/E_I$  instead of  $\delta_f$  is that the former relates to a specific deflection per unit of inverse moment of inertia and per unit load for any particular case; the measurement  $\delta_f$  is dependent on the factors governing the magnitude of the deflection—for example, the distance between the nearer outer pin and the fracture, the moment of inertia and the load.

In cases 8 and 9 the ratio  $s/E_I I_f$  is plotted in figure 20. To judge from their physical constitution the value of  $I_f$  should lie on the positive side close to the mean of  $I_{app}$ , for the male cases ( $0.94 \text{ cm}^4$ ). This would give a value about  $1.0 \text{ cm}^4$  for  $I_f$ .

ABLE 12 Recorded deflection of the fractured ( $v_{tot}$ ) and sound tibia ( $v_t$ ) during the course of healing, and the corresponding values of  $s/E_f$  (Italic numbers are extrapolated values)

FIGURE 20 Upper.—The ratio  $s/E_f$  as a function of time

Lower.—The inverse ratio ( $E_f/s$ ) as a function of time

The slope of the curves for the various cases indicates the rate of healing, expressed as a decrease in specific deflection and as an increase in stiffness of the callus, respectively.

The rate of healing can also be expressed in terms of the increase in the stiffness of the callus with time. When the deflection within the callus tends to zero—that is to say, when the deflection of the fragments accounts for nearly the whole of the total deflection of the tibia— $E_f$  tends to high values. Curves of  $E_f$ 's as a function of time are shown in figure 20.

The limits within which full weight bearing was started or clinical stability of the fracture was first noted are given in the two figures.

In four cases, 4, 32, 33 and 37, a slight increase in deflection was found to have occurred between two examinations (Table 12). In three of these cases the measurements in question were performed after full weight bearing had begun, and at most a small reduction in deflection would be expected; however, the values do not differ by more than can be ascribed to the error of the method. In the fourth case, no. 33, the explanation may be the same, although here it is at the second measurement that the increase was recorded. It could then have its explanation in extremely slow healing in the interval; but, again it might also be due to the random error of the method.

At three examinations an increase of more than 10 per cent was recorded. In case 12 the deflection was 25 per cent greater after 53 weeks than after 47; this increase must probably be ascribed to a reduction in the stability of the fracture. The long period of immobilization had resulted in stiffness of the knee and ankle and the cast was therefore removed and physiotherapy given. When, after the fifty-third week, a knee cast had been furnished and weight could be put on leg, the stability increased.

In case 18 the corrective osteotomy was followed by delayed union. The second, third and fifth values showed increases in deflection of 8, 7 and 9 per cent, whereas the fourth value indicated a reduction of 35 per cent. Here, too, the figures probably represent the true state of affairs; for during the first three measurements and between the fourth and the fifth there was no signs of progress in healing and it is probable that a pseudarthrosis was in the course of formation. For some reason—perhaps an increase in the load on the transverse fracture while the PTB cast was being worn—signs of stabilization were noted between the third and the fourth measurements. No further measurements of the deflection have yet been made.

In case 25 the deflection measurements were followed immediately by operations to hasten healing in the extremely mobile fracture, with a consequent change in the experimental conditions between the two measurements.

## *VII. Discussion*

### ACCURACY OF THE METHOD

The observed deflection of the bone contains an error that is dependent on the reliability of the measuring instrument. A further error is that inherent in the principle of the method, which is strictly applicable to a simple beam, whereas here we are concerned with a body of irregular shape and structure, composed, moreover, of biological tissue.

The total measurement error of the registration unit was  $\pm 1.2$  per cent. There is a systematic error of the method by virtue of the bending of the instrument and the local resilience of the bone around the pins; this error was calculated at 39 and 29  $\mu\text{m}$  at pin distances of 24 and 21 cm, respectively. To obtain an impression of this local resilience measurements were made of the displacement in various materials, namely, pieces of spruce wood, ebonite, oak and laminated bakelite. The respective displacements were 36, 27, 21 and 10  $\mu\text{m}$ . It may be inferred that the resilience of the pins is dependent to some extent on the physical properties of the various bones. This means that the application of a constant correction will increase the deviation of the values obtained in the calculation of the modulus of elasticity.

It is difficult to obtain a secure hold for the pin tips in bone with a thin cortex. Two attempts were made to replace the ordinary pins that had perforated the cortex with ones having threaded tips, which would be expected to give a better hold in the cortex. The values then obtained were the same as those values extrapolated from the curve.

The variation in the shape of the tibia and its heterogenous structure affect the determinations of both deflection and moment of inertia. From a visual estimate of the direction of the principal central axes of the moment of inertia of the section at different levels on 10 specimens and from an integrator determination in one specimen (Fig. 3) it would appear that these axes are practically parallel. It is only in the condylar area and near the malleolus that the principal central axes change direction; here the cross section is closer to a circle and, since the difference between the

maximum and the minimum moments of inertia of the section is small, the directions of the axes are of relatively little importance. The anterior crest has a sigmoid course and, as can be seen in figure 3, it twice intersects the plane of the principal axes. On section +12 the tuberosity of the tibia lies on the medial side of the principal central axes and on section +6 the crista anterior just passes across to the lateral side and then, in section -6, returns to the medial side. Thus, the torsion due to any twisting of the tibia's bending plane for the minimum moment of inertia may be neglected. On the other hand, the angle between the bending plane of the instrument and that for the minimum moment of inertia of the tibia when the longitudinal axes are parallel can decrease the observed deflection by up to 3 per cent. When the bending planes intersect and when they are translated and the longitudinal axes of the instrument and the tibia are kept mutually parallel, the deflection due to pure bending is increased by a torsional component; this amounts to about 2 per cent of the observed deflection.

Of greater importance, however, is the position of the middle pin. This should be the same for different measurements on the same bone, but this ideal is not always achieved. One of the reasons why a change in level of the middle pin has taken place is the difficulty of determining the contour of the medial malleolus, especially when the ankle is swollen. An attempt was made to retain the marking from one occasion to the next in order more easily to identify the sites for the pins. The most effective procedure was to fill in the old marks after the cast had been removed and before the bone was sterilized.

The deflection of the fractured tibia would presumably be affected by stress in the surrounding tissues, by any swelling of the leg and by the fluid content of the bone tissue (Sedlin & Hirsch, 1966). Opinions differ on whether the bone might be hydraulically strengthened, through the effect of the blood pressure or muscle contraction (McPherson & Juhasz, 1965; Swanson & Freeman, 1966). As, however, the significance of these factors is small and probably essentially the same for the different tibias it may be disregarded in the evaluation of the stability of the fracture.

The determination of the moment of inertia from eqn. [8] incurred a small measurement error, and the reproducibility was satisfactory. If the variation of the moment of inertia along the tibia is taken into account an even more reliable expression for the modulus of elasticity for a single observation is obtained. This was done by calculating the moments of inertia from other approximation formulae as eqn. [8] at different levels of the tibia, thereby obtaining an individual and more correct constant in eqn. [9].

The ratio  $s/E_f$  is estimated on the basis of several assumptions and approximations. The line of fracture varies and the length of the callus, the modulus of elasticity and the moment of inertia of the callus are none of them properly defined measures;  $s$  and  $E_f$  are used solely as an aid in determining the additional deflection caused by the callus of the fractured bone, and insofar as the callus cannot be regarded as a short beam or spring joint, these two terms cannot be considered to represent the real length of the callus or its modulus of elasticity.

In the mathematical model the viscous element, its variation with time, and the shear in the callus are disregarded. Nor is it entirely correct to assume that the recorded deflection of the bone fragments are identical with that of the sound tibia  $v$ , having the same systematic error of measurement for the fractured and the sound tibia (see eqn. [12]).

Because of metabolic and circulatory changes, however, this would result in a smaller value of  $\delta_f$ . Experiments on laboratory animals have shown that the healing of fractured bone is accompanied by changes in the physical properties of bone substance. The resistance of the tibia condyle to compression has been found to be lower for the bone with the fractured shaft (Nilsson & Smith, 1969).

Any variation in the ratio  $s/E_f$  is due chiefly to a change in the value of  $E_f$ . According to Henry *et al.* (1968) there is a linear relationship between the stiffness and the breaking strength of the damaged leg. In bending experiments on the rabbit in which one radius had been fractured surgically, these authors showed that during the course of healing the ratio between the ultimate breaking strengths of the fractured and sound radii varied directly as the ratio between the stiffnesses of the fractured and sound radii. The slope of the line was 0.48; that is to say, when the stiffness ratio was unity the strength ratio was about 0.5.

This would mean that when the recorded deflections of the fractured and the intact tibia are equal, the ultimate bending strength of the callus is half of the intact tibia at the same level. In the experiments on rat tibia, Wray & Goodman (1963) found that the breaking strength 65 days after the surgically produced fracture was greater for the fractured than the sound tibia, and after the 80th day the difference was statistically significant.

From the curves of  $s/E_f$  as a function of time in figure 20 (upper) it is seen that the specific deflection of the callus during the course of healing decreased at a varying rate. The curves of  $E_f/s$  as a function of time show that the increase in stiffness of the callus also occurs at a varying rate (Fig. 20, lower part). According to the study by Henry *et al.*, when there is no

deflection of callus, that is, when  $\delta_1 \approx 0$ , its ultimate breaking strength is one half that of the sound tibia bone at the same level. This would mean that up to the breaking point the callus becomes more resistant to bending forces; but there is no deflection of the fractured tibia through any weakening at the fracture site. Thus, during the further healing of the fracture the ultimate breaking strength will increase while the flexural rigidity remains constant. Clinicians consider that in general a fracture is healed, when the stiffness has been recovered. However, as the mineralization of the callus is then still incomplete it would appear that the strength goes on increasing until osseous consolidation is complete and the bone structure fully restored.

### CLINICAL VALUE OF THE METHOD

In cases where union is delayed or pseudarthrosis is suspected it is necessary to examine whether healing can be expected at all. Just what is to be gained from an operation to hasten the process is not always obvious. Most workers assess the indications for surgery on the basis of the time that has elapsed since the fracture occurred, but a long interval does not necessarily mean that the development of the stability of the fracture has stopped and it is this that should decide whether an operation should be performed. Without an objective knowledge of the stability of the fracture, it is impossible to decide whether an operation is indicated. The method reported not only provides the means for resolving this dilemma; it also enables an objective evaluation of different forms of treatment to be made.

An experienced investigator requires about 30 minutes to perform a determination of the deflection on both legs, with the accompanying radiographic examination. To appraise the development of the stability in a single case, however, it is enough to measure the deflection of the fractured bone under the same conditions two or three times over a convenient period, and each measurement will require only 10 minutes or so. In over 900 pin insertions there were no signs of infection or subsequent irritation, or of any other complications. The examinations were performed under local anaesthetic and are painless.

The bending test technique can be applied to other shaft fractures, such as those of the femur, but then another, longer, measuring beam has been used. It may also be possible to use the method for diagnostic purposes in diseases affecting bone.

## CONCLUSIONS

The bending of the tibia *intra vitam* under a force of 5 kgf can be determined in a single measurement to an accuracy of 5 per cent for men and 8 per cent for women.

The minimum moment of inertia of the tibia can be found in a single measurement to an accuracy of 5 per cent.

An *intra vitam* determination of the modulus of elasticity of the tibia can be made in a single measurement to an accuracy of 10 per cent, while for young males in sound health the error incurred in the measurement of the modulus of elasticity was 5 per cent.

The values obtained for the modulus of elasticity are probably on the high side because it was impossible to determine the moment of inertia in spongy bone.

The method is intended primarily for patients with fractures of the tibia shaft. Of the 133 measurements performed on fractured tibias there were only 3 where a straightforward interpretation of the value could not be made.

## VIII. Summary

The object of this investigation was to devise a method for obtaining an objective measure of the stability of a fracture of the tibia shaft during the course of healing.

An instrument has been designed with which the deflection of the bone can be registered as a function of the applied force.

The deflection of a bone is dependent on the moment of inertia of the section and the modulus of elasticity. A procedure has been evolved for determining the moment of inertia from a radiograph. It is thus possible to compare the deflection of various bones in terms of the varying modulus of elasticity in bending.

The accuracy of the method was examined on 20 pairs of autopsy specimens in 40 patients with tibial shaft fractures and in 9 voluntary subjects.

During the course of healing the gap between the fragments is filled with callus, whose physical properties gradually change towards those of bone. This implies a decrease in the deflection due to the weakness of the callus. As healing progresses the stiffness of the callus increases. On the basis of the values obtained from measurements carried out with the described method an expression has been deduced by means of which it is possible to compare the degree of healing in terms of quantities that are equivalent to the stiffness of fracture callus.

The clinical series consisted of 26 men and 14 women with a fracture of the tibia shaft; in most of them union was slow. The first stability measurement with the method was made, on average, 19 weeks after the fracture, and determinations were continued until full loading of the fractured leg was possible—on average 33 weeks after the fracture.

Altogether 133 such determinations were performed on fractured tibias; in only three could no definitive conclusions be drawn as regards the development of stability.

The clinical application of the method for examination of the fracture was instructive and facilitated the evaluation of the course of healing. The measurements were performed ambulatory under local anæsthetic. In more

than 900 cases there was no infection or other complication. The examination took on average 30 minutes.

In the case of delayed union the appraisal of the stability of the fracture by means of the method can be of value in deciding whether to resort to an operation in order to hasten union.

## *IX. Acknowledgements*

The design of the method of measurement, the construction of the measuring instrument, and the solution of the problems associated with the electronic registration and the experimental part of the investigation were performed at the Department of Medical Engineering, Karolinska Institute; the clinical part of the study was carried out at the Department of Orthopaedic Surgery, Karolinska Institute, Stockholm.

The theoretical analysis of the mechanics of the tibia was performed in collaboration with Christer Swerup, Civ. ing. Department of Physics, The Royal Institute of Technology, Stockholm.

The statistical analysis was performed under the guidance of Bo Lindström, M.D., the Department of Medical Physics, Karolinska Institute, Stockholm.

To all the persons without whose participation this study would not have been possible I wish to offer my sincere thanks.

Financial support received from the insurance company Folksam and through the Karolinska Institute from the State research grant for doctoral research I wish gratefully to acknowledge.

## FOREWORD

*Medullary nailing* is used throughout the world in all technically advanced countries. This method has defended its position extremely well through thirty years of experience and its use is increasing all the time. From the manufacturers we know that millions of these « medullary rods » have been sold.

The strength of the nail depends on its diameter. It increases with about the 4th potential of the transverse measurement. The medullary cavity is frequently too narrow to allow the introduction of a medullary nail of sufficient weight-bearing capacity. Not until *the method of widening the bone canal with long drills* was used, was it possible to produce a mechanically stable intramedullary osteosynthesis.

Since 1950 many surgeons engaged in traumatology, including members of the Swiss Arbeitsgemeinschaft für Osteosynthesefragen (A.O.), have used this technique. However, in many countries, for example U.S.A., the method is strongly opposed on the basis that it can cause considerable injury. Strangely enough *not one single experimental investigation has been published on this extremely important question of reaming and nailing*, in spite of the fact that this method has been used clinically for more than twenty years. The authors, S. Ölerud, G. L. Lorenzi and G. Dankwardt-Lillieström, deserve great merit for the present research work and we owe them appreciation for penetrating the problem in such an extensive, precise and thorough way.

Gerhard Kuntze

## INTRODUCTION

From the mechanical point of view it is of obvious advantage, as many surgeons realise, to treat certain diaphyseal fractures by the intramedullary nailing method. In earlier years, several different authors advocated various techniques of intramedullary fixation (Lambott 1913, Hey Groves 1918, Rush & Rush 1937). The method of Küntscher, however, has had the greatest success, and nowadays intramedullary nailing is generally linked with his name. It was in 1939 at a meeting of the Medical Society of Kiel that Küntscher first presented his concept of this procedure and introduced the spring-acting clover leaf shaped nail.

Eleven years later, in 1950, Küntscher proposed an important modification of this original method by introducing reaming of the medullary cavity. This meant that large contact surfaces between the nail and the inner cortex could be obtained, permitting the use of bigger and stronger nails. The size of the reamer used could also serve as a guide as to the most suitable diameter of the nail, and the risk of the nail getting locked was eliminated. Increased stability added to the value of this method and extended its use. The Küntscher type of intramedullary nailing, both with open and closed techniques and with different characteristics of the nail (Uffreduzzi 1942, Kaessman 1966, Wesely 1968, Schneider 1968), is still gaining increasing interest all over the world, 30 years after its introduction.

The principles of Küntscher-nailing are largely known and have often been emphasized by other authors, including Lorenz and Jorg Bohler. It seems surprising, however, that intramedullary nailing with reaming of the medullary cavity, which, though technically more extensive, is more stable and more efficient from the mechanical point of view, has not been more generally accepted by orthopaedic surgeons. But we consider that this relatively new idea, of reaming of the medullary canal, deserves deeper research in the experimental field. Danckwardt-Lillieström (1969a) found, on reaming, that marrow from

## INTRODUCTION

From the mechanical point of view it is of obvious advantage, as many surgeons realise, to treat certain diaphyseal fractures by the intramedullary nailing method. In earlier years, several different authors advocated various techniques of intramedullary fixation (Lambott 1913, Hey Groves 1918, Rush & Rush 1937). The method of Küntscher, however, has had the greatest success, and nowadays intramedullary nailing is generally linked with his name. It was in 1939 at a meeting of the Medical Society of Kiel that Küntscher first presented his concept of this procedure and introduced the spring-acting clover leaf shaped nail.

Eleven years later, in 1950, Küntscher proposed an important modification of this original method by introducing reaming of the medullary cavity. This meant that large contact surfaces between the nail and the inner cortex could be obtained, permitting the use of bigger and stronger nails. The size of the reamer used could also serve as a guide as to the most suitable diameter of the nail, and the risk of the nail getting locked was eliminated. Increased stability added to the value of this method and extended its use. The Küntscher type of intramedullary nailing, both with open and closed techniques and with different characteristics of the nail (Uffreduzzi 1942, Kaessman 1966, Weseley 1968, Schneider 1968), is still gaining increasing interest all over the world, 30 years after its introduction.

The principles of Küntscher-nailing are largely known and have often been emphasized by other authors, including Lorenz and Jorg Böhler. It seems surprising, however, that intramedullary nailing with reaming of the medullary cavity, which, though technically more extensive, is more stable and more efficient from the mechanical point of view, has not been more generally accepted by orthopaedic surgeons. But we consider that this relatively new idea, of reaming of the medullary canal, deserves deeper research in the experimental field. Danckwardt-Lilliestrom (1969a) found, on reaming, that marrow from

## LITERATURE REVIEW

Since 1940, after publication of Küntscher's first reports, nailing of shaft fractures has become an accepted method of internal fixation. Although nailing had been tried by several surgeons earlier, it was the principles of Küntscher which made it practically acceptable. His development of the method in 1950 by the reaming procedure must be considered very important, because of the possibility of primary weight bearing. During recent years, though very slowly, this change in the method has been accepted increasingly by many surgeons.

Although several studies have been published concerning the problem of nailing in different long bones of various animals, no report appears to have been made dealing with the problems arising on fracture treatment with true reaming of the medullary cavity including the inner part of the cortex. The reaming procedure involves complete destruction of the medullary circulation and gives rise to new problems regarding the blood supply to the bone as a whole and to the fracture site in particular.

The literature concerning these problems deals with such different and well defined questions that they can be suitably divided as follows

- 1 Blood supply of the diaphyseal bone on nailing
- 2 Periosteal bone reaction after nailing
- 3 Reaming of the medullary cavity
- 4 Fracture stability on nailing.
- 5 Fracture stability and healing pattern.
- 6 Nailing and reaming in relation to fat embolism

### 1 BLOOD SUPPLY OF THE DIAPHYSEAL BONE ON NAILING

As pointed out by several authors in the last 15 years, the blood supply of the shaft of long bones comprises three systems: 1. Peri-

the cavity easily caused blockage of the intracortical circulation. The effect of this on fracture healing after nailing is not known. The healing pattern, especially the peripheral bone reaction, seems at times to be contradictory—in spite of complete stability a large amount of callus formation is sometimes seen.

Our interest in the Küntscher nailing method inspired us to the present experimental studies. Although we realise that results from investigations on rabbits cannot be referred directly to man, our findings will make us more aware of the problems involved when we face clinical decisions.

There are still many unsolved problems concerning intramedullary nailing, and we hope that with this work we can give some answers to the following questions:

1. What kind and grade of damage do osteotomy and nailing produce in the cortical bone when the medullary cavity has been reamed?
2. How is revascularization of the cortical bone accomplished with a stable nail well fitting the marrow cavity?
3. How does the periosteal bone formation behave under these conditions?
4. How does repair take place in the fracture gap under these conditions?

## LITERATURE REVIEW

Since 1940, after publication of Küntscher's first reports, nailing of shaft fractures has become an accepted method of internal fixation. Although nailing had been tried by several surgeons earlier, it was the principles of Küntscher which made it practically acceptable. His development of the method in 1950 by the reaming procedure must be considered very important, because of the possibility of primary weight bearing. During recent years, though very slowly, this change in the method has been accepted increasingly by many surgeons.

Although several studies have been published concerning the problem of nailing in different long bones of various animals, no report appears to have been made dealing with the problems arising on fracture treatment with true reaming of the medullary cavity including the inner part of the cortex. The reaming procedure involves complete destruction of the medullary circulation and gives rise to new problems regarding the blood supply to the bone as a whole and to the fracture site in particular.

The literature concerning these problems deals with such different and well defined questions that they can be suitably divided as follows

- 1 Blood supply of the diaphyseal bone on nailing.
- 2 Periosteal bone reaction after nailing
- 3 Reaming of the medullary cavity
- 4 Fracture stability on nailing.
- 5 Fracture stability and healing pattern.
- 6 Nailing and reaming in relation to fat embolism.

### 1 BLOOD SUPPLY OF THE DIAPHYSEAL BONE ON NAILING

As pointed out by several authors in the last 15 years, the blood supply of the shaft of long bones comprises three systems: 1. Peri-

osteal vessels, 2. Nutrient arteries, 3. Metaphyseal vessels. The importance ascribed to these different pathways has varied.

Trueta and Cavadias (1964), in a study of the blood supply of long bones, arrived at the conclusion that (under their experimental conditions) the periosteal vessels were able to nourish only the outer third of the cortex. The same authors had stated in 1955 that the nutrient artery was normally responsible for the blood supply to the largest part of the cortex. De Marneffe (1951 and 1953) considered the proximal third of the tibia to be supplied mostly from the marrow canal. The distal third got its blood supply mostly from periosteal vessels and the middle third from both sources.

Brooks and Harrison (1957) believed that, perhaps because of the connection between the two systems, the circulation of the cortex would not be severely affected by suppression of one of the two systems (Koeckenberg 1963, Rhinelander 1968).

The damage that nailing of a long bone can produce in the medullary vascular system has been widely studied.

Trueta and Cavadias (1955), who were the first to study the small vessels in experimental nailed fractures, found, on microangiography, that even if part of the nutrient artery could escape damage, numerous branches were destroyed by the nail. In Göthman's experiments (1960a) with nailing alone, the arterial system was less severely damaged. When nailing was combined with fracture, he found more extensive damage to the intramedullary vessels (1960c).

The avascularity in the cortex that can sometimes result from nailing is obviously the reason for the cortical necrosis that some authors, e.g. Trueta and Cavadias, have shown to be very extensive and to persist partly even 8 months after the surgical procedure.

The inner avascular cortex, together with still viable bone, will undergo more or less extensive resorption and rebuilding activity, with formation of cavities. This rebuilding process has been described in recent literature by Koeckenberg (1963), Trueta & Cavadias (1964), Richany et al. (1965), Johnson (1966) and Danckwardt-Lilliestrom (1969b).

## 2. PERIOSTEAL BONE REACTION AFTER NAILING

The extensive periosteal bone formation so frequently observed by different authors, both clinically and under experimental conditions, has been given various explanations.

Küntschner (1940b-1941) considered that callus was formed as a

normal phlogistic response to the injury. Griesman (1944), Sifani & Amanta (1949) and Maatz (1951) described in a clinical study the new bone formation all along the diaphysis. Their respective explanations were: the result of chemical or physical irritation, pressure of the nail against the bone, and vascular damage.

Trueta and Cavadas (1955) considered bone marrow ischaemia as a cause of the periosteal bone proliferation.

Gothman (1960b), in rabbits, found only an occasional profuse periosteal vascular reaction, and this was not accompanied by any new bone formation.

Koeckenberg (1963), like Trueta, considers that it may be due to damage to the intramedullary vessels.

Mital & Cohen (1966), in a study on rats, found that only with maximal injury in the medullary cavity was there any significant subperiosteal bone deposition.

Richany et al. (1965), in an investigation on cat femurs, destroyed the medullary cavity by introducing a pin into the canal. With further brushing and flushing the cavity was cleaned. In these experiments he found marked periosteal bone formation which he considered to be due to stasis in the periosteal vessels and oedema resulting from destruction of the medullary venous system. He remarked that the picture resembled that in hypertrophic pulmonary osteoarthropathy.

Zucman et al (1968) and Danckwardt-Lillieström (1969c) also observed periosteal bone formation, but because of their particular experimental conditions and of their original observations, their findings will be discussed under the next heading.

### 3 REAMING OF THE MEDULLARY CAVITY

Zucman et al (1968) destroyed the marrow tissue in the medullary cavity with a reamer in experiments on the rabbit tibia. He gave a very clear description of the occurrence of bone marrow fragments under the periosteal layer during the reaming, and named this « medullo hematoma ».

Zucman considered that bone marrow, pressed through the cortical channels to the subperiosteal space, played an important role as a bone marrow auto-transplant in promoting callus formation.

One of the present authors (Danckwardt-Lillieström, 1967 and 1969c) has also studied problems arising from reaming of the medullary canal. Differently from Zucman et al., but also in the rabbit tibia,

he reamed in addition the inner part of the cortex, in an attempt to reproduce the same conditions as found in clinical practice.

Danckwardt-Lillieström (1969a, 1969c) confirmed the finding of Zucman of a subperiosteal « medullo hematoma », but he also demonstrated the intracortical and subperiosteal pathways of bone marrow by lipid staining methods.

Danckwardt-Lillieström (1969c) studied the correlation between periosteal bone formation and cortical avascularity. He showed that this was due to massive embolism of intracortical canals by bone marrow and fat.

The extent of the intracortical fat embolism and consequently of bone avascularity, is dependent upon the way in which the reaming is performed.

Danckwardt-Lillieström's studies (1969c) of the pressure in the medullary cavity during reaming of the rabbit tibia revealed wide variations from the normal value (30 mm Hg). With vigorous reaming, values up to 300 mm Hg could easily be obtained in the positive field. Negative values of about 100 mm Hg were recorded during withdrawal of the reamer.

It can be expected that reaming of a closed system such as the bone marrow cavity will result in such pressure changes.

The high pressure can easily explain the intracortical and subperiosteal presence of fat observed by Danckwardt-Lillieström (1969c) and Zucman et al. (1968), respectively.

We have demonstrated that as a consequence of reaming of the rabbit tibia, marrow fat particles can very easily appear in the femoral vein (Olerud et al. 1969)

#### 4. FRACTURE STABILITY ON NAILING

The aim of fracture treatment with intramedullary fixation has changed during the last few decades.

In previous years the only intention was to maintain the axial direction of the shaft fragments (Uffreduzzi 1942), and this always required further fixation with a plaster case. In time, however, this view altered, and more rigid stability with the avoidance of any complementary fixation became the main goal. Andersson (1962 and 1965) describes the two types of nails involved as « loose-fitting » and « tight-fitting ». We consider that in most cases the Rush pin method (1949) belongs to the loose-fitting type. The same is true of the Kirschner

pin (Landelius 1951), which was used extensively some years ago in the treatment of some diaphyseal fractures.

Satisfactory intramedullary fixation can be obtained by using a fascicle of metal pins (Hackethal 1961), with which the medullary cavity is filled completely.

In 1940 Küntscher developed a new nail, which in the transverse section worked as a spring. The aim was to obtain a nail which completely fitted the marrow canal. Küntscher found that much more stability was achieved by transforming the hour-glass shape of the medullary cavity into a cylindrical shape by reaming the inner cortex and using a wider and stronger nail (1950); at the same time the number of fractures that could be treated by this method increased.

Kaessman (1966 and 1969) describes a nail with still greater stabilizing properties especially concerning the rotatory forces, and with which compression can be applied to the fracture site.

Similar devices have also been described by Fitzgerald (1966) and Vinditti and Benini (1962).

Experimental studies of loose-fitting nails have been made by Göthman (1961), Gustilo et al (1964) and Rhinelander et al. (1967). Andersson (1965) compared the healing of experimental osteotomies in dogs with loose-fitting and tight-fitting nails. Also Varma and Metha (1967) observed differences in healing between loose and tight fitting nails.

## 5 FRACTURE STABILITY AND HEALING PATTERN

Since 1949, when Denis first proposed his compression plates, many authors have devoted their attention to problems of stability in the healing of fractures (Friedenberg et al. 1952, Yamagishi et al. 1955, Bagby et al 1958 and Petrokof 1962).

After the first reports from the AO-group with the paper of Schenck and Willenegger (1963), interest in this particular problem of osteosynthesis became intense and gave rise to considerable experimental and clinical research.

Schenck & Willenegger (1963 and 1965), after stable compression plating of osteotomized dog radii, observed secondary osteones crossing the closely adapted fracture line. They considered this an ideal form of bone healing (1967).

Geiser (1963), on the contrary, considered that the cortical fracture ends became rebuilt by «creeping substitution» from the endosteal and periosteal sides. The same conclusion was drawn by Andersson (1965) and Rhinelander et al (1967).

Two of the present authors, Olerud and Danckwardt-Lillieström (1968 and 1970) also found the primary bone healing described by Schenk et al. possible in fractures fixed with compression plates in the dog tibia. This pattern of healing was only considered feasible with absolute contact of the fracture ends, where there was no room for transverse bone formation in the gap. In clinical practice it would therefore seem almost exceptional, according to these authors.

In those cases where there is a small fracture gap, the orientation of the new lamellar bone will initially be transverse. Later, it will assume a longitudinal direction as a result of the formation of longitudinal, secondary osteones traversing the fracture area.

The healing of a fracture treated with a loose-fitting nail, as studied experimentally by Göthman (1961), Andersson (1965) and Rhinelanders et al. (1967), is usually delayed in comparison with tight-fitting nails, owing to severe necrosis of the fracture ends, with frequent non-union and an abundant formation of cartilage. Similar findings have been made by many other authors under almost similar experimental conditions (Silani et al. 1949, Trueta and Cavadias 1955, Koeckenberg 1963, among others).

Andersson (1965) planned his experiments with the purpose of comparing the healing of a fracture under the different conditions created by treatment with a loose-fitting and a fully-fitting nail. With the latter type of nail he noted more rapid healing with smaller areas of necrosis, only an occasional occurrence of cartilage and frequent direct bone formation.

Trueta et al. (1955) probably also obtained very stable fixation in many cases in his studies of intramedullary nailing of the rabbit radius, and in these cases, as is evident by his photographs, he always obtained the same results as Andersson. The choice of the radius for the osteotomy obviously ensured good stability because of the integrity of the ulna and the special connections between these two bones in the rabbit.

As far as clinical experience is concerned, Küntscher (1950) considered that the more stability that could be obtained the better healing would be achieved. Reaming of the canal before nailing, to make possible the use of a stronger nail, therefore seemed to him logical.

#### NAILING AND REAMING IN RELATION TO FAT EMBOLISM

Heavy trauma, especially when resulting in fractures, always causes emboli of marrow fat in the lungs (Backer-Grøndahl 1911, Lehman

FIG 1. - Group NS Fat-stained marrow embolus in the lung

FIG 2 - Bone marrow appearing in the transparent catheter connected to the femoral vein during reaming

& Mc Nattin 1928, Grant & Reeve 1951). The liberation of fat in this way, and the biochemical and enzymatic effects of the traumatized fat tissue, which give the clinical entity of fat embolism, have been interpreted in different ways by different authors (Peltier 1956, Bergentz

FIG 3 - Fat supernatant seen as white flecks after centrifugation of blood collected from the femoral vein . Note also the fat deposits on the walls of the test tube (to the right)

1961, Wehner 1968, Kerstell 1969, Saldeen 1969). It is conceivable that a large marrow embolus in the lungs might directly diminish the pulmonary circulation with a fatal outcome

Kerstell found, in experimental fractures in dogs followed by retrograde flushing of the lungs, that pulmonary fat emboli consisted only

of tissue fat and no plasma fat component. Küntscher is certainly aware of the risk of embolism and advocates very careful hammering of the intramedullary nail. Hackethal (1961) considers that the use of a tourniquet is always extremely important for the avoidance of

FIG 4 - May Grunwald-Giemsa staining of blood smear. Marrow conglomerates in the peripheral blood

fat emboli with the Bündelnagelungsmethod. Peltier (1956) found a tourniquet useful in preventing fat emboli in orthopedic surgery.

Palmer (1951) and Bohler (1968) suggest that nailing should be avoided in all cases with signs of the fat embolism syndrome, so as not to develop it further.

& Mc Nattin 1928, Grant & Reeve 1951). The liberation of fat in this way, and the biochemical and enzymatic effects of the traumatized fat tissue, which give the clinical entity of fat embolism, have been interpreted in different ways by different authors (Peltier 1956, Bergentz

## MATERIAL AND METHODS

### PREMISLS

The studies of Danckwardt-Lillieström (1969a-c) mentioned above, with reaming of the rabbit tibia, showed that large areas of avascular cortex were produced, with considerable variation between different animals. The reason for this was found to be that marrow particles liberated by mechanical forces were pressed into the cortical canal due to an increase in intramedullary pressure which was produced during the reaming procedure, causing embolism and blockage of the cortical circulation (Fig. 5) and subperiosteal fat deposition (Fig. 6). In the following this investigation is referred to as experiment NS (Exp. NS).

In order to avoid such a pressure increase and to reduce the extent of marrow embolism, the medullary contents were evacuated by suction before and during the reaming through a drill-hole made in the ventral part of the distal tibial metaphysis (Danckwardt-Lilliestrom et al.,

Fig 5 - Fat stained material filling the intracortical canals

Lange (1954) and Lechner and Schuster (1963) reported fatal cases, as also did Mörl (1967), who described 9 cases of fat embolism among 17 deaths out of 452 patients subjected to intramedullary nailing. Rokkanin et al. (1969) found cases of fat embolism, verified histologically by skin biopsies, among 116 cases of medullary nailing.

On reaming in clinical work Wehner (1968) observed a remarkable pressure rise in the medullary cavity.

On reaming under experimental conditions, Danckwardt-Lillieström (1969a-c) observed fat emboli caused by increased intramedullary pressure within the intracortical canals as well as in pulmonary tissue (Fig. 1).

Zucman (1968) describes the superiosteal medullo-hematoma after reaming of the medullary cavity.

On cannulating the femoral vein, Olerud et al. (1969) observed marrow tissue components in blood samples during a reaming procedure (Figs. 2, 3 and 4).

TABLE I.

Mean values, with standard deviations, of percentage of muscular cortex (PAC) in groups NS (non-suction group) and S (suction group), and also the differences in PAC between the groups, and their significance. The table also shows the number of animals in the respective groups.

Obs	Group NS			Group S			Difference NS - S	
	time weeks	No of animals	PAC M    ± SD	No. of animals	PAC M    ± SD		M	t-value
1		11	21.5    15.68	5	6.2    3.40		15.3	3.22 **
2		15	20.7    14.33	5	7.1    1.95		17.6	3.54 **
4		14	16.1    12.50	2	1.6    0.79		15.4	4.33 ***

The table shows that the standard difference was very high in Exp. NS and very low in Exp. S. The figures for Exp. S show that revascularization took place between the second and fourth weeks. This process was completed more quickly in Exp. S than in Exp. NS. In the latter experiment similar values for revascularization were not attained until after eight weeks.

The investigation described above thus showed important differences within the cortical circulation between Exp. NS and Exp. S. In view of this finding it was considered important for the present investigation to distinguish between rabbits in which reaming was performed without previous evacuation of marrow tissue (Group NS) and those in which evacuation of marrow tissue preceded the reaming (Group S). In all the latter cases the reaming was performed with the utmost care and with continuous suction.

With these premises as a basis we started our experimental model.

## MATERIAL

The investigation was carried out on 134 male and non-pregnant female albino rabbits, 7-8 months old and weighing 2.7-3.2 kg, with a mean weight of 3.00 kg. Experience had shown this size of rabbit to be ideal because of the thickness of the cortex and the width of the marrow cavity.

Our study concerned mainly the conditions of ideal healing of a stable osteotomy after reaming and nailing. For various reasons 86 of the 134 rabbits operated on had to be excluded from the main study,

1970). Under these conditions, in the following referred to as experiment S (Exp. S), the extent of intracortical avascularity, studied with Indian Ink microangiography on transverse tibial sections, was significantly smaller. A comparison was made between the findings in the two different experiments and the results are presented in Table I.

FIG. 6 - Fat stained transverse section. Intracortical and subperiosteal fat is separating the periosteum from the cortex

The table gives the mean value and the standard difference for the percentage of avascular cortex in the two experimental groups after observation times of one to eight weeks. The difference between the values for the two series is also given for the different observation times. The degree of significance is denoted by asterisks.

solution (= approx. 30 mg Nembutal) per kg of body weight was injected into one aural vein and the needle was left in place for further maintenance doses during surgery if required. The animal was then fixed in position on a special sled-shaped operation table, as illustrated in Fig. 7.

TABLE II.

The fur was cut away and the skin cleaned and disinfected with antiseptic alcoholic solution. A curved incision was made, with a medial concavity extending from the upper part of the knee to the most distal part of the tibia, in this way exposing the entire anterior aspect of the tibia and the patellar ligament.

and therefore only 48 comprise the main material upon which the results are based.

The reasons for exclusion of the 86 rabbits will be discussed below under «Remarks on Operative Procedure» (Page 25) and «Post-operative complications» (Page 25).

The main material was grouped as follows:

Group S: Osteotomy and nailing after reaming during suction of the marrow cavity. This group consisted of 33 animals and was subdivided into 9 groups with observation times between 1 and 16 weeks.

Group NS: Osteotomy and nailing after reaming without suction. This group consisted of 15 rabbits, subdivided into 6 groups with observation times between 2 and 16 weeks.

The grouping and subgrouping of the 38 animals can be seen in Table II.

## METHODS

After weighing, the rabbits were anaesthetized with Nembutal diluted in physiological saline in the proportion of 1:1; 1 ml of this

FIG. 7 - The rabbit's leg fixed on the special sledge

solution (= approx. 30 mg Nembutal) per kg of body weight was injected into one aural vein and the needle was left in place for further maintenance doses during surgery if required. The animal was then fixed in position on a special sled-shaped operation table, as illustrated in Fig. 7.

TABLE II

S = medullary cavity suctioned

NS = medullary cavity not suctioned

The fur was cut away and the skin cleaned and disinfected with antiseptic alcoholic solution. A curved incision was made, with a medial concavity extending from the upper part of the knee to the most distal part of the tibia, in this way exposing the entire anterior aspect of the tibia and the patellar ligament.

## *Operative procedure*

### **Group S (Evacuation of marrow before and during reaming).**

Using a drill 0.5 mm in diameter, a hole was made through the anterior aspect of the distal cortex in the tibia. A plastic transparent catheter with an inner diameter of 0.4 mm, connected to a suction apparatus was then inserted through the hole into the medullary cavity (Fig. 8a). During suction the catheter was repeatedly pushed up to the upper metaphysis, and at the same time physiological saline was poured over the distal hole. When no more bone marrow was

**Fig 8 - a) Suction through a catheter in the distal hole b) Suction when reaming**

seen to be sucked through the transparent catheter, this was again pushed up as far as possible and left there (Fig. 8b).

The patellar ligament was then divided longitudinally, and the precondylar space of the upper tibial epiphysis was exposed. A quadrangular awl was then inserted manually below the patellar ligament, through the metaphysis and into the upper end of the marrow cavity where the tip of the catheter was located.

#### Group NS (Direct reaming).

The same approach was made to the medullary cavity through the proximal tibia as in group S. No distal hole was made and no suction of the medullary cavity was performed prior to reaming.

FIG. 9 - The characteristics of the reamer and the nail.

## *Operative procedure*

### **Group B (Evacuation of marrow before and during reaming).**

Using a drill 0.5 mm in diameter, a hole was made through the anterior aspect of the distal cortex in the tibia. A plastic transparent catheter with an inner diameter of 0.4 mm, connected to a suction apparatus was then inserted through the hole into the medullary cavity (Fig. 8a). During suction the catheter was repeatedly pushed up to the upper metaphysis, and at the same time physiological saline was poured over the distal hole. When no more bone marrow was

Fig. 8 - a) Suction through a catheter in the distal hole b) Suction when reaming

moistened with physiological saline, and great care was taken to avoid as far as possible any damage or stripping of the periosteum.

The nail was especially made from V.4.A. stainless steel (AISI 316). It was constructed as a compression nail for stability reasons (Fig. 9).

The nail had to be designed in such a way as to satisfy the following conditions:

- a) The curved shape of the rabbit's tibia and the need for a certain degree of elasticity demanded that the nail be constructed in three different pieces.
- b) The need for a nail which would completely fit the reamed cavity, at least at the fracture site, demanded a large cylindrical intermediate section with a diameter  $100\mu$  smaller than that of the last-used reamer. Nails with different intermediate diameters were thus used in different animals.
- c) The high rotatory forces in the rabbit's leg demanded that the curved dome shaped osteotomy should be stabilized with compression.

The osteotomy stumps were then apposed and the nail was inserted from the upper prespinal epiphyseal hole, with careful hammering on its head.

When the thicker part of the nail had engaged and fixed the osteotomy line, in group NS a hole was made 2-2.5 cm distal to the osteotomy line in the anterior aspect of the tibia.

Through this hole, and in that already existing in group S, it was possible to see the location of the end of the nail during hammering. A short pin was then passed through the cortical hole and through the distal hole in the nail and drilled into the posterior distal cortex of the tibia to fix and stabilize the nail.

The upper threaded head of the nail was then adjusted beside the patellar ligament and close to the epiphyseal plate. The nut at the top of the nail was tightened until complete stability was observed in the osteotomy line under intentional stresses.

The distal transverse pin was cut at the level of the outer cortex with a pair of steel scissors.

The patellar ligament was then sutured with single silk sutures. Only one suture was used for the tibial fascia. The skin was sewn with a continuous silk suture.

No dressings were applied to the wound, apart from a double layer

Reaming was then done in the same way in both experimental groups through the proximal hole, using ball reamers for dental surgery of diameters increasing from 1.3 mm to 3.7 mm. (For further details of the reaming technique, see Danckwardt-Lillieström 1969c). The reamers were specially adapted and firmly mounted on a special steel spring shaft, 0.3 mm smaller in diameter than the reamer (Fig. 9). They were connected via a Jacob's chuck to an electric motor with a rotation rate of 300 r.p.m. The internal diameter of the marrow canal varies greatly in different animals even when they are of the same body weight and size.

After the first bone had been removed, two further reamers were used, of diameters increasing by 0.1 and 0.3 mm. This was done in an attempt to obtain as identical experimental conditions as possible.

In this way the amount of cortical bone removed by reaming was estimated to correspond to about 8% of the total bone surface (in the transverse section and the middle third of the tibia).

During the reaming procedure it was common in group NS to find the formation of a medullo-hematoma in the layer between the bone and the intact periosteum, as described by Zucman et al. (1968) and by Danckwardt-Lillieström (1969c). This subperiosteal medullo-hematoma, in which Danckwardt-Lillieström observed large amounts of fat, can occur almost anywhere around the tibia, but is more extensive just outside the openings for the nutrient arteries and emissary veins in the posterior, fibular part of the tibia.

Always during suction in group S, washing of the medullary canal was accomplished by pouring physiological saline through the upper precondylar hole, while the catheter was withdrawn to the level of the distal hole in the tibia but not taken out. This procedure with the catheter was also carried out during reaming. In fact, all reaming in this group was done with a negative pressure in front of the reamer head.

With this technique temperature increases produced by the reamer were also avoided. No medullo-hematomas were ever seen in group S.

After reaming, the periosteum was divided transversally 0.5 cm distal to the tibio-fibular junction, leaving untouched only the anterior part covering the tibial crest, which was separated finally during the osteotomy.

The osteotomy was performed at the same level with a goldsmith saw, the blade of which was 200  $\mu$  thick. To avoid rotation the osteotomy had to be done in the form of a curve with the convexity directed upward like a «dome». During sawing, the bone was always kept

according to the technique described previously (Danckwardt-Lillieström 1969 c).

The treated left leg and the right leg were then removed and immediately deep-frozen. The greater part of the soft tissues was then removed without disturbing the periosteum, and the nail was withdrawn. The proximal and distal epiphyses were cut away and the specimens were freeze-dried until a constant weight was obtained (usually 3 days). Sections were then prepared by three different processes for examination:

1. Formalin fixation, nitric acid decalcification. Paraffin embedding, sectioning and preparation by the Spalteholz (1911) process for observation in a three-dimensional microscope.
2. Formalin fixation, nitric acid decalcification. (Paraffin embedding, sectioning and staining with the Masson technique.) Parts of the preparation were cut as frozen sections and stained with Sudan III and hematoxylin.
3. Methacrylate embedding. Sawing in longitudinal and transverse sections 0.5 mm thick, and grinding of these sections down to a thickness of between 20 and 60  $\mu$  for fluorescent light observation according to the technique described elsewhere (Olerud and Lorenzi 1969). To these undecalcified slide sections, the Goldner staining technique was also applied.

The undecalcified ground sections were also studied with polarized light as well as by a microradiographic technique.

of plastic spray. In no case was plaster applied, nor any prophylactic antibiotic treatment given.

### *Recording methods*

With special «Cristallite» Kodak X-ray film, roentgenograms were usually taken immediately after surgery and again at the end of the experiment after killing of the animal but before removal of the nail. Roentgenograms were also taken in most cases after removal of the nail. Only in the long term experiments were intermediate films taken, in order to check from time to time the healing of the osteotomy, the stability of the nail and the conditions of the bone. In all animals, at different times during the observation period, triple fluorochrome labelling was performed with Tetracycline, Hematoporphyrin and DCA Fluorescein, using the technique described elsewhere (Olerud and Lorenzi 1969 and 1970).

As shown in Table III, which gives the times of administration of the fluorochromes, the labelling of the newly formed bone covered 28 out of a total of 70 days of observation. At the end of the observation time the animals were anaesthetized again as described previously, and through a longitudinal midline laparotomy incision the abdominal aorta was exposed. This was cannulated with a plastic catheter 0.5 mm in diameter. Indian ink infusion was then performed

TABLE III.

*Labelling code (L.C.) according to which the rabbits were labelled with Tetracycline, Hematoporphyrin and DCAF [(N, N' di) carbomethyl, aminoethyl fluorescein] respectively*

Observation time in weeks	Labelling day after the operative procedure		
	Tetracycline	Hematoporphyrin	DCAF
1	1	4	7
2	6	10	14
3	10	15	21
4	16	22	28
6	26	34	42
8	36	46	56

13	47	69	91
16	52	82	112

according to the technique described previously (Danckwardt-Lillieström 1969 c).

The treated left leg and the right leg were then removed and immediately deep-frozen. The greater part of the soft tissues was then removed without disturbing the periosteum, and the nail was withdrawn. The proximal and distal epiphyses were cut away and the specimens were freeze-dried until a constant weight was obtained (usually 3 days). Sections were then prepared by three different processes for examination:

1. Formalin fixation, nitric acid decalcification. Paraffin embedding, sectioning and preparation by the Spalteholz (1911) process for observation in a three-dimensional microscope.
2. Formalin fixation, nitric acid decalcification. (Paraffin embedding, sectioning and staining with the Masson technique.) Parts of the preparation were cut as frozen sections and stained with Sudan III and hematoxylin.
3. Methacrylate embedding. Sawing in longitudinal and transverse sections 0.5 mm thick, and grinding of these sections down to a thickness of between 20 and 60  $\mu$  for fluorescent light observation according to the technique described elsewhere (Oferud and Lorenzi 1969). To these undecalcified slide sections, the Goldner staining technique was also applied.

The undecalcified ground sections were also studied with polarized light as well as by a microradiographic technique.

## RESULTS

### REMARKS ON THE OPERATIVE PROCEDURE

Of the total 134 rabbits operated on, 6 died under anaesthesia, (no pulmonary biopsies were taken in these cases).

Forty animals were needed for trial operations to obtain the most suitable level and shape of the osteotomy. A curved osteotomy line was used to prevent rotation, which otherwise easily occurred. Owing to the tendency of the concave surface to become fractured, the concavity was made on the proximal fragment, which was mechanically stronger than the distal one, partly because of the greater extent of reaming in the distal fragment.

A level just below the tibio-fibular synostosis was chosen for the osteotomy. In this area the inner layer of cortex was always reamed, and therefore the nail always fit closely in both fragments.

Owing to longitudinal infractions in 7 rabbits, occurring in the proximal segment of the tibia during compression, a cerclage wire was added in these cases (5 in group S and 2 in group NS). No difference was observed in the healing pattern in these animals in comparison with the remainder. These 7 animals were therefore included in the main material

### POSTOPERATIVE COMPLICATIONS

Fifteen rabbits sustained secondary fractures, mostly longitudinal in the upper part of the tibia, during the first days after operation, and they were therefore excluded from the material.

During the observation period 19 rabbits died of epidemic gastrointestinal infection with diarrhoea.

In group S no local infection occurred, nor any deaths from fat emboli.

In group NS there were 2 deaths from massive local infections and also 4 deaths from massive fat emboli, verified histologically. Of these latter 4 rabbits, one died just before the end of the operation and 3 during the first hours postoperatively. These deaths from fat

emboli, which thus occurred only in group NS in which reaming was performed without suction, comprised 11% of the total operated on in this group. During operation in this group a further 4 animals developed sudden dyspnoea and cyanosis. It seems highly likely that pulmonary fat emboli occurred also in these animals, which later recovered spontaneously.

#### GENERAL BODY REACTION TO THE OPERATION

The change in the mean body weight was calculated in each subgroup of groups S and NS (see Table II, p. 17). During the first week the body weight decreased in both groups. After the third week the animals in group S showed a fairly even and continuous weight increase. In group NS the body weight increase was usually slower than in group S. Also the death rate indicates that the animals in group NS were more severely affected than those in group S.

#### LOCAL REACTIONS

During the first 24 hours after operation, the rabbits held the treated leg close to their body, but after this time they seemed to use their legs in the normal way.

In group S the local reaction in the undisplaced osteotomized legs was characterized by a small spool-shaped swelling which decreased after 2-3 weeks and developed into a very small bony prominence. In group NS the swelling was more pronounced and the spool shape more elongated. After the 2nd to 3rd week the swelling was still considerable and became indurated. The time it took for the swelling to decrease was much longer in group NS.

#### ROENTGENOLOGICAL FINDINGS

In most of the rabbits a good fit of the nail in the reamed cavity was seen (Fig. 4). The curved osteotomy line was hardly visible even in the short-term experiments. In the distal part of the tibia it was also possible to compare the thickness of the reamed cortex and the non-reamed cortex, and the amount of cortical bone removed could be roughly estimated (Fig. 10). Figure 11 demonstrates the shape and level of the osteotomy line in an animal observed after the 2nd week, where the gap is widened because of the absence of callus and the movement during withdrawal of the nail. The cerclage-treated animals showed no difference in the roentgenological findings from the unfractured cases (Fig. 12).

The roentgenological healing pattern differed regularly in groups S and NS (Fig. 13). In the animals with late secondary fractures (Fig. 14) it was more difficult to distinguish between the two groups.

#### *Group S (with suction)*

The peripheral osseous formation in this group was, as a rule, very thin and was observed only at the level of the osteotomy and never along the whole tibia (Fig. 15).

The fracture line was only slightly visible after 4 weeks and in most cases had completely disappeared after 8 weeks (Fig. 16a-b). Endosteal bone formation was nearly always present and locked the nail. This could be regarded as a sure sign of complete stability (Fig. 17).

The porosity of the cortical bone as a sign of cortical remodelling which took place in the later stages of the healing can be seen in Fig. 17.

FIG. 10 - X-ray appearance just after operative procedure

emboli, which thus occurred only in group NS in which reaming was performed without suction, comprised 11% of the total operated on in this group. During operation in this group a further 4 animals developed sudden dyspnoea and cyanosis. It seems highly likely that pulmonary fat emboli occurred also in these animals, which later recovered spontaneously.

#### GENERAL BODY REACTION TO THE OPERATION

The change in the mean body weight was calculated in each subgroup of groups S and NS (see Table II, p. 17). During the first week the body weight decreased in both groups. After the third week the animals in group S showed a fairly even and continuous weight increase. In group NS the body weight increase was usually slower than in group S. Also the death rate indicates that the animals in group NS were more severely affected than those in group S.

#### LOCAL REACTIONS

During the first 24 hours after operation, the rabbits held the treated leg close to their body, but after this time they seemed to use their legs in the normal way.

In group S the local reaction in the undisplaced osteotomized legs was characterized by a small spool-shaped swelling which decreased after 2-3 weeks and developed into a very small bony prominence. In group NS the swelling was more pronounced and the spool shape more elongated. After the 2nd to 3rd week the swelling was still considerable and became indurated. The time it took for the swelling to decrease was much longer in group NS.

#### ROENTGENOLOGICAL FINDINGS

In most of the rabbits a good fit of the nail in the reamed cavity was seen (Fig. 4). The curved osteotomy line was hardly visible even in the short-term experiments. In the distal part of the tibia it was also possible to compare the thickness of the reamed cortex and the non-reamed cortex, and the amount of cortical bone removed could be roughly estimated (Fig. 10). Figure 11 demonstrates the shape and level of the osteotomy line in an animal observed after the 2nd week, where the gap is widened because of the absence of callus and the movement during withdrawal of the nail. The cerclage-treated animals showed no difference in the roentgenological findings from the unfractured cases (Fig. 12).

cortex in the later stages  
can be seen here.

FIG. 15. - Group S X-ray 8 weeks after nailing, showing a small thickening of the bone at the osteotomy site.

*Groups NS (without suction)*

The peripheral osseous formation, illustrated in Fig. 18, was often considerable and extended along the entire diaphysis. Sometimes it was interrupted at the fracture level (Fig. 20). A similar, but not quite so extensive peripheral bone reaction is shown in Fig. 19. Condensation of the new peripheral osseous tissue, which had the appearance of a new cortex, was observed in this group (Fig. 18). The original cortex appeared to be sequestered and this was most pronounced close to the fracture line. The resorption of cortex was more pronounced far away from the osteotomy line.

The cortical ends, in contact at the osteotomy line, seemed to be practically unaffected by resorption. In some cases (Fig. 21) the peripheral new bone did not bridge the osteotomy line in spite of the

FIG. 16. - Group S. X-ray 4 weeks after nailing. Almost no peripheral reaction Osteotomy line is hardly visible (a). 8 weeks after nailing: Osteotomy line still less visible (b)

weeks in most cases, there was no satisfactory bridging across the osteotomy line.

Almost all animals in group NS (BI and BII in Fig. 13) could be considered to show delayed union, at least, even if not true non-union (Fig. 21)

FIG. 20. - Group NS. X-ray 13 weeks after nailing: another extensive, less mature, peripheral reaction and delayed union. On the right the contralateral tibia.

The first vessels very soon grew into the peripheral avascular part of the cortex, however, even at the level of the osteotomy line where the periosteum had been separated from the cortex during surgery and been replaced before closure of the wound. Around the vessels

FIG 23 - Group S Spalteholz preparation 4 weeks after nailing. Almost normal intracortical circulation at the upper nail level, where the endosteal circulation is also well re-established.

penetrating the avascular cortex there was progressing resorption, seen mainly in the third and fourth weeks (Fig. 24a and b). Later in the healing process the revascularization activities involved the development of many cutter heads which usually passed through the cortex in the direction towards the osteotomy line (Fig. 25). Sometimes

## MICROSCOPICAL OBSERVATIONS

### *Vascularity and rebuilding of cortex*

The experimental procedure always resulted in total damage to the intramedullary circulation, and close to the osteotomy line also in periosteal damage. This damage, due to stripping of the periosteum around the osteotomy, was estimated to extend about 1 cm above and 1 cm below the osteotomy line. This meant total primary avascularity of the osteotomy area.

### Group S

In one preparation observed after one week the cortical ends were completely avascular (Fig. 22). In the distal and also, mostly, in the upper part of the diaphyseal cortex, far away from the osteotomy

FIG 22 - Group S, Spalteholz preparation 1 week after nailing. Complete avascularity of the cortical ends. A vascular loop is entering the osteotomy line  
x Medullary cavity

line, it was common to observe an almost normal intracortical circulation (Fig. 23). During the first week the intracortical vessels became wider. The vascular front was located at the level of the damaged and undamaged periosteum.

FIG. 25. - Group S Fluorescence preparation 4 weeks after nailing (L C. 16-22-28). Cutter heads are remodelling the cortex and progressing towards the osteotomy line

FIG. 28. - Group S. Spalteholz preparation 6 weeks after nailing. Abundance of vessels attacking the inner avascular cortex just adjacent to the nail.

these cutter heads, supplied by vessels coming from the periosteum, seemed via resorption lacunae to excavate the cortex, often the middle part (Fig. 26). The cortex could be revascularized from endosteal vessels in some cases as early as in the 2nd and 3rd weeks, but the 4th week was more usual for revascularization from this direction. These vessels penetrated the cortex especially in the region above the upper end of the nail (Fig. 27a and b). They often gave rise to resorption at the inner wall of the cortex and revascularized the inner part of it (Fig. 28).

#### Group NS

The avascularity of the cortex in this group was often very extensive. It was caused not only by the rupture of marrow vessels but also by marrow fat particles which had been forced out into the intracortical canal system. The avascularity lasted for a very long time. In a preparation six weeks after osteotomy there were still large areas without any Indian-ink filled vessels (Fig. 29).

The revascularization process of the cortex appeared to be quite different from that in group S, although in some cases the invasion of blood vessels from the periosteum close to the osteotomy line was similar.

FIG. 29a. - Group NS. Spaltholz preparation 6 weeks after nailing. Revascularization pattern. From top to bottom, 1) Outer corticalized peripheral layer; 2) large vascular lacunae; 3) vascular communications with outer revascularized cortical layer; 4) sequestered inner cortex.

FIG. 29b. - Transverse section of preparation in Fig 29a

In comparison with group S, only a few vessels seemed to enter the cortex. Other vessels joined in cavities to form wider sinusoids often located in the middle part of the diaphyseal cortex. These vascular cavities increased in size and became more elongated along the cortex, forming a kind of reticular system. The cortical bone seemed to become « dissolved » or « melted down » in a peculiar way. This resorption procedure did not present the typical appearance of pure osteoclastic activity.

In its most pronounced form this « melting » activity would divide the cortex into one central layer which in some cases was sequestered

FIG 30 - Group III Fluorescence preparation 2 weeks after nailing (L.C. 6-10-14) The red labelling shows the first bone deposition under the stripped periosteum after ten days. The activity has increased very rapidly during the next days and the bone is labelled with green on the 14th day.

completely (Fig. 29) and one outer layer which would later be included in the remodelling of the new cortex in one way or another (Fig. 29).

#### *Periosteal bone formation*

Close to the gap, where the periosteum had been incised, ingrowing vessels and cells from surrounding tissues contributed to bone

FIG 31. - Group S Fluorescence preparation 2 weeks after nailing (L C 6-10-14)  
The periosteal reaction at different distances from the osteotomy line

formation. Away from the osteotomy line the bone was only formed subperiosteally.

### Group E

In this experimental group the new bone reached a limited thickness only close to the level of the osteotomy line. The first periosteal reaction was seen to have occurred on the 3rd to 4th day in the hemato-porphyrin-labelled bone, up to a distance of 0.5 cm from the osteotomy line. This newly formed bone often bridged the osteotomy line after the first week (Fig. 30). In the 1st and 2nd weeks it had the typical appearance of trabecular bone, later usually forming primary osteones in several layers. From the level of the osteotomy line, these osteones decreased in number and thickness along the diaphysis and finally ended in a layer of superficial lamellar bone far away from the osteotomy line (Fig. 31). Later, in the 6th to 8th weeks, the outer layer of trabecular bone underwent remodelling by superficial resorption of the ridges and by lamellar bone formation around the vessels in the intertrabecular spaces, a process which resulted in condensation, or corticalization, of the outer layer of the periosteally formed bone (Figs. 32 and 33). In the innermost layer just outside the cortical bone and close to the osteotomy line, resorption activities predominated, with typical Howship's lacunae eroding the outer cortex and resorption of the inner part of the newly formed trabecular bone (Fig. 33). This process terminated in the formation of limited cavities which then tended to unite. The tendency of these cavities was to move slowly into the cortex as a result of resorption from the central cortical wall and accretion of bone to the inner side of the peripheral wall.

### Group NS

The periosteal bone formation was always very pronounced all along the diaphysis (Fig. 34). In comparison with group S, the bone formation began some days later. In some cases it showed even distribution along the diaphysis, but in the early stages it was also possible to see parts of the bone without any subperiosteal bone formation. Close to the osteotomy line, newly formed bone was seldom seen on the surface or in the gap. This was observed, however, in one preparation after 2 weeks (Fig. 35). During the time up to the 4th week the newly formed periosteal bone could reach enormous proportions, in some cases up to 8 times as much as observed in group S (Fig. 34).

FIG. 32. - Group S. Fluorescence preparation 6 weeks after nailing (L.C. 26-34-42). The outer peripheral reaction is undergoing resorption. Condensation is clearly demonstrated by the triple fluorochrome linear labelling. In the inner part just in contact with the nail a layer of green labelled bone can be seen

FIG 33 - Group S Fluorescence preparation 11 weeks after nailing (L.C. 26-34-42) Resorption cavities in the inner part of the peripheral bone

FIG 34 - Group S (left). Fluorescence preparation 4 weeks after nailing. The enormous peripheral reaction in group NS (right) attains almost 3 times the size of that observed in group S (L. C. 16-22-28). The arrow indicates the osteotomy line

FIG 35 - Group NS. Fluorescence preparation 4 weeks after nailing (L. C. 16-22-28). At the fracture line the periosteal bone formation is interrupted by vascular granulation tissue with wide resorption areas. Note the large vessels

This bone consisted of long spicular trabeculae. Close to the fracture gap these trabeculae were orientated towards the gap, but further away along the diaphysis the orientation was perpendicular to the cortex as if very strong bone induction was taking place.

FIG. 36. - Group NS. Fluorescence preparation 6 weeks after nailing (L. C. 26-34-42) Bridging external callus, no activity in the fracture ends.

The periosteal reaction gave newly formed woven bone, which moved like a wave towards the osteotomy level with increasing observation time. In between the « waves » from each side, fibrous tissue, large vessels (Fig. 35) and sometimes cartilage cells were seen. This observation could, of course, be interpreted as a demonstration of instability, but very often, in other parts of the same tibia, periosteal

FIG 37. - Group NS - Fluorescence preparation 13 weeks after nailing (L.C. 47-69-91) Peripheral bridging corticalization. Rebuilding and sequestration of old cortex. At the bottom the site of the nail is seen.

callus could be seen to bridge the osteotomy line (Fig. 36). In the following weeks, beginning from the end of the 6th, the newly formed periosteal bone underwent final maturation. Outside the osteotomy gap, this process followed the same pattern and stages as in group S. The bone maturation and formation of cystic resorption cavities showed only quantitative differences (Fig. 37).

#### *Intramedullary reaction*

When reaming, owing to the irregular shape of the medullary cavity, only parts of the innermost cortical layers will be removed (Fig. 38). The *a* zones (see figure) of the medullary cavity are not totally removed by the reamer, but obviously the vessels there must be severely damaged. The nail itself usually fits very well in the distal part of the canal, but will be free from contact with the cortex at several points in the upper part of the diaphysis (Fig. 38).

The revascularization of the medullary cavity and of the inner part of the cortex usually follows three pathways:

1. from the undisturbed upper and lower metaphysis along the *a* zones,

This bone consisted of long spicular trabeculae. Close to the fracture gap these trabeculae were orientated towards the gap, but further away along the diaphysis the orientation was perpendicular to the cortex as if very strong bone induction was taking place.

FIG. 36. - Group NS. Fluorescence preparation 6 weeks after nailing (L. C. 26-34-42) Bridging external callus, no activity in the fracture ends

The periosteal reaction gave newly formed woven bone, which moved like a wave towards the osteotomy level with increasing observation time. In between the « waves » from each side, fibrous tissue, large vessels (Fig. 35) and sometimes cartilage cells were seen. This observation could, of course, be interpreted as a demonstration of instability, but very often, in other parts of the same tibia, periosteal

2. directly through the cortex, mainly observed in the upper part of the diaphysis,
3. through the fracture gap where such exists.

### Group S

The appearance of vessels in the medullary cavity, growing through the gap, was already observed after the first week (Fig. 39*a* and *b*). A network of vessels in the  $\pi$  zones, partly coming from the upper

FIG. 38. - Schematic diagram illustrating: I) reamed areas of inner cortex (*b*) and non-reamed parts of the medullary cavity (*a*); II) the fitting of the nail and the free zones where the medullary circulation has free space.

end, was seen after the third week. At the same time, single vessels appeared in the *b* zones between the reamed cortex and the nail.

From the third week onwards newly formed bone was seen in the *a* zones immediately adjacent to the nail. The progression of bone formation in the section shown in Fig. 40 can easily be timed. Common also was the observation of vessels directly crossing the cortex and growing almost as far as the nail where they sometimes divided in the form of a T, which embraced the nail (Fig. 41). The further remodelling of the cortex proceeded in a typical manner, consisting of erosion of the inner cortical layer with simultaneous deposition of lamellar bone around the nail (Fig. 42).

FIG 42. - Group S Fluorescence preparation 4 weeks after nailing (L. C. 16-22-28) Remodelling of the inner cortex with simultaneous erosion and deposition of bone lamellae along the nail. Note the rebuilding in the outer cortex (bottom)

The process of erosion of the inner part of the cortex resulted in the confluence of many different cavities surrounding the newly formed bone around the nail (Fig. 43). These cavities contained blood vessels and new bone marrow with marrow cells and fat cells. The vessels, often as large as vascular lacunae, frequently seemed to be in communication with the metaphyseal vascular system, which, after the

FIG. 40 - Group S. Transverse section. Fluorescence preparation 4 weeks after nailing (L.C. 16-22-28). Newly formed bone enclosing the nail is labelled with yellow (zone a), red and green (zone b). Note the resorption of peripheral ridges.

FIG. 41. - Group S. Transverse section. Fluorescence preparation 8 weeks after nailing (L.C. 36-46-56). Centrally a large vessel with a lacunar appearance is traversing the cortex and divides into two branches embracing the nail. Intense remodelling in the outer part of the cortex.

end, was seen after the third week. At the same time, single vessels appeared in the *b* zones between the reamed cortex and the nail.

From the third week onwards newly formed bone was seen in the *a* zones immediately adjacent to the nail. The progression of bone formation in the section shown in Fig. 40 can easily be timed. Common also was the observation of vessels directly crossing the cortex and growing almost as far as the nail where they sometimes divided in the form of a T, which embraced the nail (Fig. 41). The further remodelling of the cortex proceeded in a typical manner, consisting of erosion of the inner cortical layer with simultaneous deposition of lamellar bone around the nail (Fig. 42).

FIG. 42. - Group S Fluorescence preparation 4 weeks after nailing (L.C. 16-22-28). Remodelling of the inner cortex with simultaneous erosion and deposition of bone lamellae along the nail. Note the rebuilding in the outer cortex (bottom).

The process of erosion of the inner part of the cortex resulted in the confluence of many different cavities surrounding the newly formed bone around the nail (Fig. 43). These cavities contained blood vessels and new bone marrow with marrow cells and fat cells. The vessels, often as large as vascular lacunae, frequently seemed to be in communication with the metaphyseal vascular system, which, after the

4th week, usually took a more active part in the supply of the inner cortex with blood vessels (Fig. 44). In still later stages the new bone around and close to the nail became thicker, and also acquired a more mature appearance (Fig. 45).

### Group NS

The intramedullary reaction in this group was usually extremely delayed, except in some rare cases, where the intracortical circulation had not been so severely disturbed (compare zone *a* in Fig. 381).

## *The nail and the bone formation*

### **Group S**

Very soon after the vessels reached the nail, usually in the 3rd or 4th week, it became surrounded by newly formed bone (Figs. 40, 42 and 44) which increased successively in amount and maturation (Fig. 43). The bone formed a cast, so to speak, which embraced all three parts of the nail (Fig. 45 A and B). This bone cast around the nail can be regarded as an expression of the total stability of the fixation system.

FIG. 45 B. - Corresponding preparation investigated with microradiography. Note the well adapted bone cast of the nail.

### **Group NS**

Up to the 10th week no new bone was usually formed around the nail in this group. In sections examined after the 13th week, incomplete bone casts with a considerable amount of fibrous tissue between the bone and the nail were found. This finding can probably be regarded as a sign of instability.

### *Osteotomy line*

The intramedullary nail, because of its central position, should be the ideal device for achieving equal compression all along the circumference of the contact surfaces of the osteotomy. This condition was not always obtained in our experiments. This was partly due to the slightly curved shape of the rabbit tibia in the longitudinal axis, while

the nail was purely cylindrical and was unable to bend in its central part. The curved osteotomy itself cannot always be ideal for good apposition in spite of the fact that it prevents rotation. For these reasons we usually observed in the same animal an osteotomy which was well apposed and had complete contact on the one side of the tibia, but with a gap on the other side.

### Group S

The first signs of healing of the osteotomy line started with vascularization. Vessels could appear in the gap as early as in the first week (Fig. 46). When the bone contact is absolute, vascular invasion from the periosteal side is very difficult. In these areas an ingrowth of

The healing is almost completed in the outer layer of cortex. The innermost  
part, where the last osteone has passed through, is still undergoing remodelling.

vessels with simultaneous bone resorption was not observed before the 3rd week. This resorption was almost immediately followed by formation of lamellar bone in the form of primary osteons. The resorption area was U-shaped with formations resembling cutter heads, occurring on both sides of the line, which was often respected as if resorption of the fracture surfaces was more difficult (Fig. 47). The

FIG 47. - Group S. Fluorescence preparation 6 weeks after nailing (L C. 26-34-42). U-shaped area of resorption and deposition of the cutter head type

osteotomy line, filled out in this way by bone, was later crossed by secondary osteons in the 5th to 6th week.

The U-shaped bone remodelling with resorption and bone formation in the gap eventually connected the two fracture ends. This

osteotomy line, filled out in this way by bone, was later crossed by secondary osteones in the 5th to 6th week.

The U-shaped bone remodelling with resorption and bone formation in the gap eventually connected the two fracture ends. This

After the 10th week most of the osteotomy line was filled with new transversely formed bone, and many longitudinal osteones crossed the osteotomy line, including that part where there was close contact. In this way the remodelling of the osteotomy line would become completed, even if some small parts of it remained unchanged for a very long time (Fig. 49 and 50).

FIG 51. - Group S Fluorescence preparation 3 weeks after nailing (L.C. 10-15-21) Wide osteotomy gap early invaded by vessels. Yellow labelled bone (10th day) is seen at the entrance of the gap Lamellar bone is deposited during the red through green period Note the retrograde vascularization of the cortical ends.

The wide gap was quickly invaded by new vessels coming from the network produced by the peripheral vascular reaction. Primarily

process came to a stop in its progression along the osteotomy line, after which the newly formed bone underwent maturation. Parts of the closely adapted osteotomy line remained unchanged until it became rebuilt by traversing secondary osteones. Termination of the revascularization process was a very frequent finding and we cannot give any acceptable explanation for it.

The secondary osteones usually appeared earlier in the upper fragment than in the lower. A frequent observation was termination of the excavation by the cutter heads for the secondary osteones at the osteotomy line, where they widened to form the shape of an elephant's foot (Fig. 48).

This finding suggests that the osteone head was searching for a canal in the opposite fragment for its further growth on the other side. This pattern fits well with the common observation that a new secondary osteone usually grows along the old devitalized canals. The crossing of osteones from the distal fragment was observed later in the healing process, after the 8th to 10th week.

FIG. 50. - Group 2. Fluorescence preparation 16 weeks after nailing (L.C. 52-82-112). Osteotomy line still visible. A large secondary osteone crosses the line in the centre of the cortex. ## Group NS

The most impressive finding was the lack of vessels and bone in the gap. In Spalteholz preparations examined after the 2nd and also the 4th week, there was an almost total absence of vessels in the cortical ends (Fig. 54).

This is remarkable in comparison with the rapid revascularization observed in group S. Even after the 6th week, when some bone would appear in the osteotomy line, the osseous communication between the fragments consisted mainly of ■ bridging periosteal cuff.

The cortical ends always remained totally «cold» and avascular without any signs of vessels entering the cortex (Fig. 55), and very seldom cutter heads were seen there even in the 10th week. The characteristic secondary osteones so often observed during this time in group ■ seemed to have been replaced by the formation of large resorption intracortical cavities. At this time—the 10th week—interfragmental new bone connected the ends of the necrotic cortical bone in some cases (Figs. 56 and 37).

woven bone was formed around these vessels. This bone was later condensed by the formation of primary osteones and sometimes also by secondary osteones. These transformed the newly formed bone into mature lamellar bone disposed transversally along the gap, usually between the 3rd and 6th weeks (Fig. 51).

The bone was often firmly fixed to the borders of the gap, which was often found to be eroded by osteoclastic resorption arches (Fig. 51).

After the 3rd to 4th week, vessels from the gap sometimes, though not often, found their way into the cortical ends, forming a typical pattern, which is shown in Fig. 51. Here, as well as in the well adapted osteotomy line, secondary osteones crossed the gap after the 6th week, remodelling the bone already formed and restoring the longitudinal architecture of the diaphyseal bone (Fig. 52).

In some cases a wedge-shaped defect was found at the outer part of the osteotomy line, probably caused by the sawing and not an effect of resorption. This defect was filled at an early stage with woven bone, which was later rebuilt in the same way as the bone in the wide gap (Fig. 53).

FIG. 56 - Group NS - Fluorescent preparation 16 weeks after nailing (L C 52-82-112). The cortical ends have been largely resorbed and the old bone is replaced by large cortical cavities. There is, however, some interfragmentally formed bone visible at the level of the arrow, and the cortical end contact is defective. The periosteally formed bone is condensed to a strong reliable fragment uniting bridge (right).

## DISCUSSION

Nailing has for many years been a well accepted and valuable method in the treatment of some diaphyseal fractures. Improvements of the technique, however, have been based more on clinical experience than on experimental studies.

Reaming of the medullary cavity with the use of a stronger nail has increased the number of fractures suitable for this treatment. This method has greatly improved the stability and has made immediate weight bearing possible. These are very important factors in the treatment of diaphyseal fractures. Opponents of the method often argue that this mode of treatment causes extensive damage to the circulation of the bone and, as a consequence, increases the risk of complications such as infections and delayed union. They also point out that the method may increase the swelling of the leg and cause circulatory disturbances (Nylander and Semb 1970). The opponents therefore consider that the advantages of the method do not compensate for its disadvantages.

On nailing, and especially on reaming, the medullary vessels in the diaphyseal part of the bone are destroyed. This, together with the periosteal damage caused by a fracture or by an experimental osteotomy, can result in some damage to the cortical circulation.

Previous experiments on rabbits have shown that reaming in the medullary cavity often produces a high intramedullary pressure that forces bone marrow into the intracortical canals, where it may obstruct a large part of the circulation (Danckwardt-Lillieström 1969c).

If, however, the reaming is performed after previous evacuation of the marrow contents and during suction of the medullary cavity, the cortical avascularity can be reduced to a very great extent (Danckwardt-Lillieström et al. 1970).

With the present experimental work we have tried to evaluate in what way an osteotomy, firmly stabilized with a compression nail, will heal in the presence of different degrees of cortical damage provoked by the reaming.

The « dome-shaped » osteotomy just below the level of the tibio-

In earlier experiments (Olerud et al. 1969) it was found that blood samples from the femoral vein during reaming contained numerous marrow particles.

The soft tissue reaction around the osteotomy in group S was small and of short duration in comparison with group NS, where it was sometimes very extensive and persisted for a long period.

The local clinical findings at the different observation times in the different groups corresponded with the roentgenological and microscopical patterns. The small degree of periosteal bone formation in group S was very similar to the reaction observed in experiments with intermediate avascular fragments stabilized by a compression plate in dogs (Olerud & Danckwardt-Lillieström 1970). The bone was formed almost exclusively close to the osteotomy line, and the first formed woven bone very quickly rebuilt to lamellar bone. In this group we were unable to confirm the generally accepted profuse periosteal bone formation after medullary nailing described from experimental findings by Trueta and Cavadias (1955), Andersson (1965), Richany et al. (1965), Rhinelanders et al. (1967) and many others and from clinical observations by Küntscher (1962) and Böhler (1949).

In group NS where the aim was to obtain a high intramedullary pressure during reaming, the considerable soft tissue swelling corresponded to a large amount of callus all along the diaphysis. Such a periosteal reaction was found in some animals by Danckwardt-Lillieström (1969c) on reaming the medullary cavity of the rabbit tibia without fracture. This supports the opinion that these periosteal reactions do not depend upon instability. In spite of the considerable peripheral bone formation, clearly visible roentgenologically, the new bone did not always bridge the osteotomy line all around the bone. Some parts of the line were, however, often firmly bridged. This proves that the absence of bridging in other parts is not due to lack of stability.

Our technique with the «dome-shaped» osteotomy fixed with the compression nail assured us of complete stability of the osteotomy in both groups. Stability is considered by many authors (Yamagishi et al. 1955, Friedenbergs 1952, Rhinelanders et al. 1967, Küntscher 1962) to be a factor which diminishes peripheral bone formation. In our study, however, although good stability was achieved in almost all animals, the large peripheral reaction was only found in group NS. We consider, therefore, that the peripheral bone formation depends, at least under our conditions, much more on subperiosteal marrow deposition, eli-

-fibular synostosis, stabilized by a compression nail, has proved to be a suitable model.

The aim of the compression nail is to obtain such good stability that the vascular proliferation in the osteotomy area will not be mechanically disturbed. The compression itself certainly does not induce bone formation, but only maintains the stability, especially by preventing rotation. The compression forces sometimes resulted in slight deformation of the osteotomy ends, but in our opinion the deformity does not produce any disturbance of the cortical canals outside the deformed area.

In group S, since the fatty marrow had been evacuated previously, the impairment of the cortical circulation in the middle part of the diaphysis was due mainly to disruption of vascular communications between the marrow and the cortex. Another reason for the impaired cortical circulation in group NS was the subperiosteal medullo hematoma (Zucman et al. 1968, Danckwardt-Lillieström 1969c). This separates the periosteum and disrupts the vascular communications between the periosteum and cortex, which result in further damage to the cortical bone in this area. This medullo hematoma may have a similar effect to that of autologous bone marrow transplantation as described by Burwell (1966).

In our two main experimental groups, group S and group NS, a definite difference in pattern was observed throughout, not only as regards the cortical vascular damage, but also in the general and local clinical appearance, radiological findings and the microscopical healing pattern.

The operative procedure in itself causes stress in the organism as a whole, as has been pointed out by many authors. In spite of the fact that these rabbits were still in the age of growth, they stopped growing for a period of about 20 days. This was observed in both groups. There were, however, some differences between animals undergoing the more crude operation—the non-suction group—and those in which the operation was more careful—the suction group. The former animals appeared to be more affected generally, with, on the whole, a slower weight increase, perhaps due to a larger degree of local trauma and also possibly due to an effect of the distribution into the organism of marrow particles, mobilized by the reaming in this group.

The death rate from fat emboli in the non-suction group was 11%, and a further 10% showed clear signs of the fat embolism syndrome but survived.

two groups in the revascularization and bone formation at the fracture line. In group S vessels already appeared in the first week, and were followed almost immediately by bone formation, so that the gap in the X-ray pictures had almost disappeared by the 4th to 5th week. A period of 4 to 6 weeks is considered normal for a rabbit tibia to heal (Varma and Metha 1967). In group NS, however, the osteotomy line remained clearly visible and with little reaction even up to the 13th and even the 16th week. The consolidation in these cases depends almost solely upon the enormous periosteal bone formation, and in spite of this bone formation a reliable union between the osteotomy ends will seldom take place. Real bone union never seems to occur between the fracture ends when the intracortical circulation is blocked by fat emboli. In group S there was also vascular invasion from the gap into the osteotomy ends. Also this phenomenon was never seen in group NS. This indicates that there must be some factor in the cortex, probably the fat in the intracortical canals, which, mechanically or chemically, may prevent the invasion of vessels. Supporting the chemical influence is the fact that vessels in group NS would sometimes not even grow into the fracture gap.

Depending upon the size of the osteotomy gap, woven bone or lamellar bone is formed. In later stages, i.e. the 6th to 8th week, the line will be crossed by secondary osteones. Small areas in the region of close contact will, however, still remain unrebuilt after a very long time—up to the 16th week. The reason for this might be that the mechanically very stable nail will eliminate space polarizing factors as a stimulus for total cortical remodelling (Frost 1963, Schenck 1965).

In group S the nail was very soon surrounded by newly formed bone, and later it was «locked» even more closely by thicker mature lamellar bone. At the same time the endosteal part of the original cortex was extensively resorbed but replaced by stable beams which connected the bone cast around the nail with the original cortex, and the nail would never loosen. The nail will in this way also give «stress protection» to the bone, which can explain the spongialization and delay in final remodelling of the cortex, which was very slow in the later stages.

In group NS, where the bone healing was extremely retarded, the anchoring of the nail was very poor. This was certainly due to the impaired vascular situation. The nail had to function as a stabilizing factor for a longer period of time because of the delay in consolidation.

mination of the marrow circulation and cortical bone necrosis than on instability, though this can be a contributory factor.

The often extensive periosteal bone formation in the Bündelnagelung method (Hackethal 1961) may fit well with this opinion, since a large amount of the marrow content will be forced out from the medullary cavity by the steel pins.

The revascularization of the cortical bone which starts at an early stage from all vascularized areas of the surrounding soft tissue, the periosteum, cortex and marrow cavity, occurred in different ways in the two groups. In group S it followed two lines, firstly by connection with pre-existing vessels, in the same way as described by Birch and Brånemark (1969) in revascularization of full thickness skin grafts and by Olerud and Danckwardt-Lillieström (1970) in experiments with avascular cortical fragments, and secondly by the cutter head procedure. In this respect the periosteum plays the largest role in furnishing the blood supply through the cortex to the vascular front. The original centrifugal flow in the cortex furnished by the nutrient artery will be replaced by a centripetal flow from the periosteal vessels. Such a conversion of blood flow has been described by many authors (Brookes 1960, Rhineland and Bargary 1962, Cavadias and Trueta 1965, Ladanyi et al. 1965) from studies with different experimental models. By vessels perforating the cortex and via vessels passing through the fracture line and by a contribution from the metaphyseal systems, the endosteal circulation will be partly restored.

Revascularization of the large avascular areas of cortex in group NS seemed to be very difficult. Central to the sparsely vascularized outer part of the cortex, cystic cavities were formed which later enlarged and became confluent. The cavities were furnished from vessels increasing in size through the outer cortex. The cortex central to the cavities was not invaded by vessels, but only eroded from the surface. This may have been due to blockage of the bone canals by fat. The decomposed fat may act as a toxic factor and prevent normal revascularization. After some time parts of the inner cortex became sequestered and at least partly resolved, and this can be seen in the X-ray pictures. The cortical damage in this group showed wide interindividual variations and as a consequence of the conditions described above there were important quantitative differences. The endosteal revascularization also exhibited great variety in timing and intensity.

The osteotomy ends in both groups, S and NS, were primarily avascular. In spite of this, definite differences were seen between the

two groups in the revascularization and bone formation at the fracture line. In group S vessels already appeared in the first week, and were followed almost immediately by bone formation, so that the gap in the X-ray pictures had almost disappeared by the 4th to 5th week. A period of 4 to 6 weeks is considered normal for a rabbit tibia to heal (Varma and Metha 1967). In group NS, however, the osteotomy line remained clearly visible and with little reaction even up to the 13th and even the 16th week. The consolidation in these cases depends almost solely upon the enormous periosteal bone formation, and in spite of this bone formation a reliable union between the osteotomy ends will seldom take place. Real bone union never seems to occur between the fracture ends when the intracortical circulation is blocked by fat emboli. In group S there was also vascular invasion from the gap into the osteotomy ends. Also this phenomenon was never seen in group NS. This indicates that there must be some factor in the cortex, probably the fat in the intracortical canals, which, mechanically or chemically, may prevent the invasion of vessels. Supporting the chemical influence is the fact that vessels in group NS would sometimes not even grow into the fracture gap.

Depending upon the size of the osteotomy gap, woven bone or lamellar bone is formed. In later stages, i.e. the 6th to 8th week, the line will be crossed by secondary osteones. Small areas in the region of close contact will, however, still remain unrebuilt after a very long time—up to the 16th week. The reason for this might be that the mechanically very stable nail will eliminate space polarizing factors as a stimulus for total cortical remodelling (Frost 1963, Schenck 1965).

In group S the nail was very soon surrounded by newly formed bone, and later it was «locked» even more closely by thicker mature lamellar bone. At the same time the endosteal part of the original cortex was extensively resorbed but replaced by stable beams which connected the bone cast around the nail with the original cortex, and the nail would never loosen. The nail will in this way also give «stress protection» to the bone, which can explain the spongialization and delay in final remodelling of the cortex, which was very slow in the later stages.

In group NS, where the bone healing was extremely retarded, the anchoring of the nail was very poor. This was certainly due to the impaired vascular situation. The nail had to function as a stabilizing factor for a longer period of time because of the delay in consolidation.

The resorption around the nail will win over the bone formation, with instability as a result. The pseudarthrosis in our rabbits may have been due to this reason. Probably in some cases the cause of delayed healing and pseudarthrosis occurring in clinical practice (L. Böhler 1953, Bürkle de la Camp 1958) can be referred to these factors.

## CONCLUSIONS

This experimental work aimed at answering some fundamental questions in the treatment of fractures with reaming and nailing. Though this type of surgery has many aspects, and many problems still remain untouched, we believe that the questions we posed in the introduction can be given some answers:

To the cortical damage, produced by reaming of the medullary cavity the osteotomy adds total avascularity of the osteotomy ends. The nail itself does not seem to produce any further damage to the cortical circulation.

When the avascularity is due to severance of the vascular communication the revascularization process is rapid and occurs by connection with preexisting intracortical vessels or by cutter head formation. The latter process is more or less complete and takes place without any major cyst formation in the cortex. If the avascularity is due to fat emboli in the intracortical canals, the revascularization is very slow and incomplete. Large cystic cavities are formed, which become confluent and often sequestrate parts of the inner layer of the cortex.

With minor cortical damage under stable conditions, limited periosteal bone formation almost invisible on X-ray pictures is seen. With a larger extent of cortical damage, even under stable conditions, considerable periosteal bone formation creates a new cortex.

Under stable conditions and with minor cortical damage, the repair is characterized by immediate bone formation in the osteotomy gap (if such exists), followed by remodelling of the cortex and fracture area by secondary longitudinal osteones. The nail itself, fully fitting the fracture region in the medullary cavity, does not in any way impair the bone formation and healing of the osteotomy because of the good vascularity supplied in the early stages mainly from the periosteal vascular system.

With extensive cortical damage due to marrow emboli, the healing of the osteotomy line is very slow and incomplete or may fail owing to impaired revascularization of the osteotomy ends and the

pronounced resorption in this region. If consolidation of the fracture occurs, this will rely on the condensed periosteal bone which acts as a stabilizing cuff around the diaphysis at the osteotomy level.

In the former case, with less cortical damage, the nail will be enclosed firmly, at the same time as bone is laid down in the osteotomy gap. Under the second condition, when large cortical damage is present this enclosing process is greatly delayed. Resorption forces are more pronounced and there is a serious risk that the nail will become loose before the circumferential repair is strong enough to maintain the stability. Instability may then often result in pseudarthrosis.

## Acknowledgements

My sincere thanks are due to all those who have helped me with this investigation.

To my present chief, Professor John Sevastikoglou, M. D., Head of the Department of Orthopaedic Surgery, University Hospital, Umeå. Without his constant help in various ways this investigation would not have been possible.

To my former chief, Professor Ragnar Magnusson, M. D., Head of the Department of Orthopaedic Surgery, Regional Hospital, Linköping, who originally suggested this investigation.

To Docent Rudolf Lemperg, M. D., for his helpful criticism and advice.

To Docent Seved Ribbing, M. D., Head of the Department of Diagnostic Radiology II, Regional Hospital, Linköping for his help with the roentgenologic investigation.

To Dr. Anders Movin and Dr. Paul Junghagen for help with the examination of the radiographies.

To Sten Holmqvist, C. E. and Hans Vallberg, F. K., UMDAC, for help with the computation of the material.

To Lennart Gustavsson, F. K. and Erik Arvidsson, F. K. for help with the statistics.

This investigation was supported by grants from the University of Umeå and Östergötlands Landsting, Linköping.

## CHAPTER I

### Introduction

Articular injuries, including operative procedures, are generally regarded as influencing the occurrence of degenerative arthritis of the affected joint. The connection between intra-articular procedures and secondary degenerative arthritis can hardly be denied, but this experience is almost exclusively based on clinical empiricism and not on concrete facts.

Ruptures of the semilunar cartilage of the knee are the most common intra-articular injuries and consequently, their removal is the most usual intra-articular procedure. The relation between removal of the semilunar cartilage of the knee and the development of degenerative arthritic changes in the joint is a controversial subject. This applies to both the frequency of occurrence of degenerative arthritis following the operative procedure and the effect of different factors, — such as trauma, duration of the preoperative history, age at the time of operation, — on the development of degenerative arthritis.

A number of follow-up examinations of, and reports on, patients who had been subjected to meniscectomy, showed clear-cut results with regard to the occurrence of degenerative arthritis after removal of the semilunar cartilage of the knee. However, the frequency rates stated by various authors and the importance they attach to the different factors in the development of degenerative arthritis vary very widely. As a rule the results reported are based on the authors' own material, where, to a certain extent, subjective evaluation cannot be entirely excluded; the results are also often based on small series and on the analysis of only one or of a few factors which are regarded as playing a role in the development of secondary changes in the joint. Furthermore, only a few authors confirm their results on the basis of statistical analysis.

Authors who recommend partial resection of an injured semilunar cartilage, consider that its total extirpation changes the statics and dyna-

mics of the operated knee to such a high degree that the late results are less satisfactory than after partial resection (Dengler 1938, Weisbach 1942, Hübner 1943, L. Böhler 1955, Krömer 1955, Streli 1955, Jonasch 1964). The advocates of total meniscectomy consider on the other hand that the "regenerate" after partial resection is qualitatively and functionally worse than after total extirpation. There is, therefore, a greater risk of a new rupture and of degenerative arthritis after partial resection than after total meniscectomy (Bürkle de la Camp 1936, Andreesen 1937, Magnus 1938, Mandl 1940, Schaefer 1953, Frosch 1956, Smillie 1962, Schilling 1963 and 1965, Strelec & Wozelka 1964, Zippel 1964, Herschmann 1965, Jelinek 1965, Springorum 1966).

There are also authors who state that one has to decide from case to case the type of operation to be performed (Hagemeyer 1955, Leuschner & Weickert 1964, Tapper & Hoover 1969).

Access to a large number of patients, who had been subjected to meniscectomy during almost half a century, and personal follow-up examination of the majority of the cases have made it possible to analyze objectively the results obtained, with long observation periods. The size of the material has further made it possible to treat statistically the obtained results with consideration of different factors which might influence the occurrence of degenerative arthritis. For these reasons a detailed report on this material was considered well justified in order to meet the need for concrete and clear-cut answers to the following main questions:

- to what extent is the operated knee affected by roentgenological signs of degenerative arthritis compared with the nonoperated joint; and if there are any differences in the occurrence of degenerative arthritis are these significant?
- to what extent have the patients subjective discomfort and objective symptoms after removal of the semilunar cartilage of the knee?
- which factors could possibly influence the fate of the meniscectomized knee?
- is partial resection or total extirpation to be preferred when choosing the method of operation?

## CHAPTER II

### Material

The basic material comprised all the patients who, during the period 1921—1960, were operated at the Regional Hospital in Linköping, Sweden, for rupture of the semilunar cartilage of the knee, in all 718 persons. Fig. 1 shows the number of operations during the different 10-year periods. Up to 1950 these patients were operated at the Department of General Surgery, but since the autumn of 1950 all injuries of the semilunar cartilage were operated on at the Department of Orthopaedic Surgery. Examination of the patients was performed during 1965 and the first half of 1966, by the author himself. Therefore, only patients who were resident in the reception area of the Regional Hospital in Linköping at the time of the follow-up could be included in this investigation. No selection was made of the material investigated.

The method adopted when trying to trace the patients was based partly on the county register and partly on inquiries to the parish registrar's offices. No information could be obtained regarding 49 persons. Seven patients were resident abroad. The parish registrar's offices furnished information on 42 deceased patients. Seventeen of these had been operated during the period 1921—1940 and 25 during the period 1941—1960. Moreover, 123 patients were traced, who at the time of the follow-up examination were living outside the reception area of the Regional Hospital in Linköping. In all, 497 persons were found who could be considered for follow-up investigation. On receiving an invitation 480 of them answered by attending for a follow-up examination. This represents 66.8 per cent of the total number of operated patients and 96.5 per cent of those who were known to be living in the reception area.

Table 1 shows the number of persons from the entire material who were investigated, as well as the distribution of total or partial meniscectomies and so-called "double-operations", i. e. cases where more than

mics of the operated knee to such a high degree that the late results are less satisfactory than after partial resection (Dengler 1938, Weisbach 1942, Hübner 1943, L. Böhler 1955, Krömer 1955, Strelt 1955, Jonasch 1964). The advocates of total meniscectomy consider on the other hand that the "regenerate" after partial resection is qualitatively and functionally worse than after total extirpation. There is, therefore, a greater risk of a new rupture and of degenerative arthritis after partial resection than after total meniscectomy (Bürkle de la Camp 1936, Andreesen 1937, Magnus 1938, Mandl 1940, Schaefer 1953, Frosch 1956, Smillie 1962, Schilling 1963 and 1965, Strelec & Wozelka 1964, Zippel 1964, Herschmann 1965, Jelinek 1965, Springorum 1966).

There are also authors who state that one has to decide from case to case the type of operation to be performed (Hagemeyer 1955, Leuschner & Weickert 1964, Tapper & Hoover 1969).

Access to a large number of patients, who had been subjected to meniscectomy during almost half a century, and personal follow-up examination of the majority of the cases have made it possible to analyze objectively the results obtained, with long observation periods. The size of the material has further made it possible to treat statistically the obtained results with consideration of different factors which might influence the occurrence of degenerative arthritis. For these reasons a detailed report on this material was considered well justified in order to meet the need for concrete and clear-cut answers to the following main questions:

- to what extent is the operated knee affected by roentgenological signs of degenerative arthritis compared with the nonoperated joint; and if there are any differences in the occurrence of degenerative arthritis are these significant?
- to what extent have the patients subjective discomfort and objective symptoms after removal of the semilunar cartilage of the knee?
- which factors could possibly influence the fate of the meniscectomized knee?
- is partial resection or total extirpation to be preferred when choosing the method of operation?

## CHAPTER II

### Material

The basic material comprised all the patients who, during the period 1921—1960, were operated at the Regional Hospital in Linköping, Sweden, for rupture of the semilunar cartilage of the knee, in all 718 persons. Fig. 1 shows the number of operations during the different 10-year periods. Up to 1950 these patients were operated at the Department of General Surgery, but since the autumn of 1950 all injuries of the semilunar cartilage were operated on at the Department of Orthopaedic Surgery. Examination of the patients was performed during 1965 and the first half of 1966, by the author himself. Therefore, only patients who were resident in the reception area of the Regional Hospital in Linköping at the time of the follow-up could be included in this investigation. No selection was made of the material investigated.

The method adopted when trying to trace the patients was based partly on the county register and partly on inquiries to the parish registrar's offices. No information could be obtained regarding 49 persons. Seven patients were resident abroad. The parish registrar's offices furnished information on 42 deceased patients. Seventeen of these had been operated during the period 1921—1940 and 25 during the period 1941—1960. Moreover, 123 patients were traced, who at the time of the follow-up examination were living outside the reception area of the Regional Hospital in Linköping. In all, 497 persons were found who could be considered for follow-up investigation. On receiving an invitation 480 of them answered by attending for a follow-up examination. This represents 66.8 per cent of the total number of operated patients and 96.5 per cent of those who were known to be living in the reception area.

Table 1 shows the number of persons from the entire material who were investigated, as well as the distribution of total or partial meniscectomies and so-called "double-operations", i. e. cases where more than

TABLE 1. The distribution of the whole material. Patients available and those not available for follow-up examination are included. M = males, F = females.  
 $\% = M + F$

Patients	Total number		%	Total meniscectomy		Partial meniscectomy		"Double-operated"	
	M	F		M	F	M	F	M	F
Followed-up	422	58	66.8	384	56	19	2	19	0
Not " "	212	26	33.2	198	25	8	0	0	1
Total	634	84	100.0	582	81	27	2	25	1

one semilunar cartilage was operated on in the same patient. In 6 cases among the "double-operated" both semilunar cartilages in the same knee were removed. In 13 patients one semilunar cartilage had been operated on in both knees. In the remaining 461 patients only one semilunar cartilage had been operated on. Twenty-one patients underwent partial resection and 440 total extirpation of the meniscus. It is these last-mentioned 440 patients who underwent total meniscectomy that will be reported on as the main material in what follows. Furthermore, a brief account will be given of the patients subjected to partial resection and those who underwent a "double-operation". Very shortly, the problem of re-operation on the same semilunar cartilage will also be dealt with.

### *Comments on the material*

Previous reports on large materials, as for instance Zippel's series (1964), with 1,360 operated patients, usually give data only on sex and age distribution as well as, among other information, the side of the semilunar cartilage operated on, but they are not based on a follow-up examination. In table 2 follow-up investigations reported by different authors are summarized. Some of these follow-ups are based wholly or partially on questionnaires sent to the patients, and are thus, a report only on the patient's conception of his complaint. With regard to the number of re-examined persons, the present material is comparable with other follow-up series.

TABLE 2 *Materials, period of observation and method of judging the results, according to different authors*

## 1. AGE DISTRIBUTION

This refers to the age of the patients at the time of operation. Fig. 2 and 3 show the age distribution both for the entire material comprising 718 persons and for all the 480 patients who were followed up. For the "double-operated" the age at the time of the first operation is given. The mean age for the entire material was  $31.9 \pm 0.46$  years, and for the patients who were followed-up  $33.5 \pm 0.53$  years. Thus there was no appreciable difference in age distribution between the entire material and the patients who were followed-up.

FIG 2 Age distribution of the total number of meniscectomies

FIG. 3 Age distribution of the follow-up cases. Percentages at the top refer to the relation between the followed-up patients and the total number of patients belonging to each 10-year period

### Comments

The age distribution in the material of some authors is shown in table 3. It will be observed that most authors have a peak in their material during the third decade, which agrees with the condition in the present series. The mean ages stated correspond also with those given in this material. The comparatively low percentage of followed-up persons younger than 20 years at the time of the operation is probably due to the fact that in the entire material a large number of military servicemen were included, who at the time of the investigation were living outside the reception area.

TABLE 3 *Age distribution at operation, according to different authors*

Authors	Ave- rage age	Under years						Over 60 %
		21 %	21 - 30 %	31 - 40 %	41 - 50 %	51 - 60 %		
Key & Strömberg (1930)	48		29.2	35.4	22.9	12.5	0	0
MacAusland (1931)	34.9		23.8	32.1	17.8	14.0	10.0	2.3

Springorum (1966)	150		90 per cent between 29-39 years					
Jackson (1968)	577		8.0	25.0	29.0	25.0	11.0	2.0
Hubner (1943)	35	30						
Huckell (1965)	134	30						
Tapper & Hoover (1969)	213	32						

## 2. SEX

As shown in table 1 the entire material consisted of 84 women and 634 men, giving a ratio of females to males of 1 : 7.54. Among the followed-up persons 58 were women and 422 men, and here the ratio women to men was 1 : 7.27.

### Comments

In other series the ratio females to males varied widely, as demonstrated in table 4. It is difficult to find any explanation for this. The ratio reported in many other materials corresponds with the ratio in the present series.

TABLE 4. Ratio females to males according to different authors.

Authors	Ratio	Authors	Ratio
Frising (1930)	1:3.5	Aarstrand (1954)	1:7
Key & Strömberg (1930)	1:7	Sevastikoglou (1954)	1:7.7
MacAusland (1931)	1:1.85	Scheibe (1963)	1:3.1
Abrahamsen (1933)	1:1.3	Strelec & Wozelka (1963)	1:3.9
Andersson (1934)	1:22	Kuhnel (1964)	1:9.76
Rostock & Runge (1937)	1:2	Zippel (1964)	1:5.5
Efskind (1939)	1:1.2	Day (1966)	1:5.1
Brechling (1942)	1:4	Jackson (1968)	1:8.4
Sjövall (1942)	1:5	Tapper & Hoover (1969)	1:4

## 3. OPERATED MENISCUS

Among the 718 patients who were operated on in the entire material, 607 underwent medial and 137 lateral meniscectomy, which represents a ratio lateral to medial 1 : 4.43. Among the 480 persons who were followed-up 417 had had medial and 82 lateral meniscectomy, or lateral to medial 1 : 5.08.

### Comments

Table 5 shows a wide variation as to the ratio lateral to medial meniscectomies in different materials with higher frequency of medial. No explanation for these variations could be advanced. Hashimoto (1958) reported a higher incidence of lateral than medial and he explains this

divergent relation in the Japanese by their manner of living. The relation in the present material, however, is in good agreement with most of the other reports.

TABLE 5. *Ratio lateral to medial according to different authors*

Authors	Ratio	Authors	Ratio
Frising (1930)	1:6.2	Hashimoto & al. (1958)	3.2:1
Key & Strömberg (1930)	1:15	Wynn Parry & al (1958)	1:2.2
MacAusland (1931)	1:3.8	Scheibe (1963)	1:13.6
Abrahamsen (1933)	1:7	Strelec & Wozelka (1963)	1:7
Andersson (1934)	0.23	Kühnel (1964)	1:10.9
Aleman & Friberg (1934)	1:6.1	Zippel (1964)	1:3.8
Efskind (1939)	1:5	Leuschner & Weickert (1964)	1:4
Brechling (1942)	1:8.5	Herschmann (1965)	1:5
Sjovall (1942)	1:3.5	Barta & Perjés (1965)	1:14
Aarstrand (1954)	1:4.7	Day (1966)	1:3.3
Strelz (1955)	1:7.1	Ritchie (1966) children	1:2.9
Barfod & Bierring (1956) males	1:5	Jackson (1968)	1:3.7
females	1:2	Tapper & Hoover (1969)	1:5.1

#### 4. SIDE

In the entire material the ratio left to right knee was 1 : 1.20 and among the persons followed-up 1 : 1.26.

##### Comments

No large differences between left and right operated knee were found in the material of other authors (table 6). Also in the present material both knees were affected to almost the same extent by injuries of the semilunar cartilage

TABLE 6 *Ratio left to right according to different authors*

Authors	Ratio	Authors	Ratio
Sjovall (1942)	1:1.38	Wynn Parry & al (1958)	1:1.2
Fuss (1951)	1:0.71	Zippel (1964)	1:1.13
Strelz (1955)	1:1.13	Day (1966)	2:1

## 5. TRAUMA

Rupture of the semilunar cartilage may occur without the injured person being able to state any definite trauma. It has, therefore, been assumed that nontraumatic ruptures are due to a high degree to degenerative changes in the semilunar cartilage. In this material it was found that the injury of the semilunar cartilage was clearly associated with trauma in 80 per cent of the cases both in the entire material and in the subjects who were followed-up. Information on several traumata in the same patient has not been specially noted, despite the fact that in a number of cases several injuries were mentioned. In athletes, on the other hand, there may have been information on only one injury, although it is known that, repeated traumata of the knees are usual, e. g. in footballers.

### *Comments*

The frequency of traumatic ruptures of the semilunar cartilage reported earlier (table 7) and that reported in the present investigation were about the same.

TABLE 7. *Percentage traumatic ruptures of the semilunar cartilage according to different authors*

Authors	Per cent	Authors	Per cent
Key & Stromberg (1930)	93.7	Barfod & Bierring (1956)	85.7
Brechling (1942)	75.0	Scheibe (1963)	77.9
Sjovall (1942)	91.6	Barta & Perjés (1965)	79.8
Nitter (1946)	97.6	McLaughlin (1966)	92.8
Aarstrand (1954)	73.2		

## 6. INJURIES IN ATHLETES

Twenty-eight per cent of all operated patients related the rupture of the semilunar cartilage directly to injury occurring in the course of athletics. The majority of these patients were men.

### *Comments*

Other authors had an appreciably higher percentage of injuries connected with athletics (table 8) than that shown in this material. The number of patients stated in another Swedish investigation (Sjovall, 1942) agrees

best with the percentage for the present material. It is difficult to decide, however, whether this is due to special Swedish conditions or to a certain selection in the material of other authors. One explanation of the differences may be, that other authors have apparently calculated the percentage of injuries occurring in the course of athletics on the basis of meniscectomies performed on patients with a clear trauma in the history and not, as in this material, as a percentage of the entire number of cases.

TABLE 8 *Frequency of lesions of the semilunar cartilage due to sport trauma according to different authors*

Authors	Per cent	Authors	Per cent
Raess (1930)	60.7	Aarstrand (1954)	48.2
Spira (1933)	50.0	Bestle (1955)	40.5
Rostock & Runge (1937)	47.1	Wynn Parry & al (1958)	69.0
Sjovall (1942)	33.0	Zippel (1964)	58.8
Nitter (1946)	57.1		

## 7. LATENCY PERIOD

The time that elapsed between the injury or the first appearance of the symptoms respectively and the time of operation — termed in this investigation the latency period — is shown in table 9 with regard to the number of cases in each time group. If data on several injuries were available

TABLE 9 *Distribution of the whole material and the followed-up cases with regard to the latency period M = males, F = females ■ = M + F.*

Latency period	Number of cases		%	Followed-up		%
	M	F		M	F

<sup>1)</sup> 17 cases operated on twice

<sup>2)</sup> 12 " " " "

## 5. TRAUMA

Rupture of the semilunar cartilage may occur without the injured person being able to state any definite trauma. It has, therefore, been assumed that *nontraumatic ruptures* are due to a high degree to degenerative changes in the semilunar cartilage. In this material it was found that the injury of the semilunar cartilage was clearly associated with trauma in 80 per cent of the cases both in the entire material and in the subjects who were followed-up. Information on several traumata in the same patient has not been specially noted, despite the fact that in a number of cases several injuries were mentioned. In athletes, on the other hand, there may have been information on only one injury, although it is known that, repeated traumata of the knees are usual, e. g. in footballers.

### *Comments*

The frequency of traumatic ruptures of the semilunar cartilage reported earlier (table 7) and that reported in the present investigation were about the same.

TABLE 7. *Percentage traumatic ruptures of the semilunar cartilage according to different authors*

Authors	Per cent	Authors	Per cent
Key & Stromberg (1930)	93.7	Barfod & Bierring (1956)	85.7
Brechling (1942)	75.0	Scheibe (1963)	77.9
Sjovall (1942)	91.6	Barta & Perjés (1965)	79.8
Nitter (1946)	97.6	McLaughlin (1966)	92.8
Aarstrand (1954)	73.2		

## 6. INJURIES IN ATHLETES

Twenty-eight per cent of all operated patients related the rupture of the semilunar cartilage directly to injury occurring in the course of athletics. The majority of these patients were men.

### *Comments*

Other authors had an appreciably higher percentage of injuries connected with athletics (table 8) than that shown in this material. The number of patients stated in another Swedish investigation (Sjovall, 1942) agrees

terial was, therefore, divided, in respect of the observation period, into the following decades:

4—13 years, 14—23 years, 24—33 years, and 34—43 years. Table 11 shows the distribution of all the subjects followed up in the different observation-period groups. It was found that in 199 cases, or 41.1 per cent, the observation period was at least 14 years. In 73 cases, or 15.2 per cent, the observation period was at least 24 years.

TABLE 11 Distribution of followed up patients with regard to observation period (in decades) M = males, F = females % = M + F.

	Total		4—13 years		14—23 years		24—33 years		34—43 years	
	M	F	M	F	M	F	M	F	M	F
Number of cases	422	58	236	45	118	8	61	5	7	0
%	100.0		58.5		26.3		13.8		1.4	

#### Comments

On account of the differences in the classification of observation periods in other reports it was not possible to compare, in tabular form, frequencies of subjects followed up in the different observation-period groups with the corresponding frequency in the present material. If, however, the frequency figures in the different observation periods given above are compared with earlier investigations (table 2), it will be found that this material is comparable with other materials with regard to the length of the observation period and to the number of cases in the different observation-period groups.

then the latency period was calculated from the first injury reported. Six months have been taken as the limit between a short and a long latency period. Many other authors have used the same limit. The number of patients in the group with a latency period exceeding 6 months was larger than the number of patients in groups 0—1 and 1—6 months. On the other hand, if all the patients operated during the first half year were taken together, it was found that these formed a somewhat larger group compared with the patients who were operated on after a latency period of half a year.

### Comments

In several reports no distribution with regard to the latency period is given. Table 10 shows the distribution reported by some authors. In a number of series a contrary relation is reported, e. g. a larger number of patients operated after a latency period of 6 months. The differences, however, are relatively small and the observations are based on materials of different size. Early diagnosis and, consequently, early operation in recent years, as well as longer expectancy prior to operation adopted by some surgeons, can also account for these differences.

TABLE 10 *Distribution of the materials of different authors with regard to the latency period*

Authors	Under 6 months		Over 6 months	
	Number	%	Number	%
Key & Strömberg (1930)	19	43.2		
Dengler (1938)	48	64.8	25	50.8
Sjovall (1942)	66	46.2	26	35.2
Barfod & Bierring (1956)	51	46	77	53.8
Herschmann (1965)	91	55.2	59	54
Jackson (1968)	210	36.4	74	44.8
			367	63.6

## 8. OBSERVATION PERIOD

In view of the fact that the follow-up investigation was begun in 1965 and all the patients operated in 1960 were included in the material, the shortest observation period was somewhat longer than 4 years. The ma-

was given in radiological reports, for example, in connection with arthrography.

*Injuries of the collateral ligaments, injuries of the cruciate ligaments, chondromalacia patellae, osteochondritis dissecans or osteoarthritis* in the knee joint in connection with the operation were recorded only in such cases where these were mentioned in the operation report.

Postoperative complications in the form of *haemarthrosis* or *persisting effusion* were noted if the hospital records contained definite information in this respect. Signs of *infection* were recorded only if, in connection with a rise in temperature, information was also given, e.g. concerning increased local temperature and/or redness in the operating area. No case of extensive supuration was recorded in the whole material.

*Postoperative fixation* with some kind of splint or circular plaster cast was only noted if this had been recorded. Similarly, the time when the patient was first allowed to bear weight, and the *duration of the post-operative hospitalization* were also recorded.

If definite information was available for *postoperative muscular training*, this was recorded as well.

The type of surgical procedure, such as partial or total extirpation of the semilunar cartilage was also noted.

## 2. FOLLOW-UP INVESTIGATION

### ■ Clinical examination

*Subjective complaints* were recorded on a standardized form in accordance with scheme I with + if the patient stated any. Each question was recorded separately. If a patient stated in answer to a question that he had considerable trouble, this was recorded by ++, and if the trouble was very pronounced with +++.

Objective findings were tested by inspection and palpation. The range of movement was measured from the maximal extended position ( $0^\circ$ ) to the maximal actively flexed position. Signs of cruciate ligament instability was tested with the knee at about  $90^\circ$  flexion position and the foot fixed. Lateral instability was tested with the knee in the extended position. To test the muscular strength of the knee the patient was asked to stand on one leg and from the maximal extended position to bend the knee to a squatting position from which he could rise without supporting himself with his hands or with the other leg. The angle between the initial posi-

## CHAPTER III

### Methods

The material was collected by studying the hospital register for the patients admitted during the years 1921—1960. A double control was obtained also by checking the operation register for the same period. All the patient records were produced, and from these summaries were made of the most important details of the case histories, of the entire operation reports and of the postoperative data, and transferred to punched cards. At the follow-up a scheme number 1 (p. 26) was used for the recording of subjective complaints, objective clinical findings, and information on the type of occupation as well as athletic activities after operation. Information whether the patient had had to change to lighter work after the operation, and the reasons for this were also noted. A roentgenologic examination was also made at the follow-up investigation.

#### 1. DATA FROM HOSPITAL RECORDS

*Lockings* were recorded only if data on these occurred in the hospital records; the frequency of the lockings was not noted.

*Effusion* was recorded only if the case records contained the relevant data or if exudate was established and recorded by the examining physician or the surgeon.

*Haemarthrosis* was noted only provided the data were connected with puncture or when operation was performed in close association with trauma.

Because in this hospital the roentgen films are usually discarded after 10 years it was only possible to record the data on *preoperative roentgenologic osteoarthritis* in those cases where information on such changes

was given in radiological reports, for example, in connection with arthrography.

*Injuries of the collateral ligaments, injuries of the cruciate ligaments, chondromalacia patellae, osteochondritis dissecans or osteoarthritis in the knee joint in connection with the operation were recorded only in such cases where these were mentioned in the operation report.*

*Postoperative complications in the form of haemarthrosis or persisting effusion were noted if the hospital records contained definite information in this respect. Signs of infection were recorded only if, in connection with a rise in temperature, information was also given, e.g. concerning increased local temperature and/or redness in the operating area. No case of extensive supuration was recorded in the whole material.*

*Postoperative fixation with some kind of splint or circular plaster cast was only noted if this had been recorded. Similarly, the time when the patient was first allowed to bear weight, and the duration of the post-operative hospitalization were also recorded.*

*If definite information was available for postoperative muscular training, this was recorded as well.*

*The type of surgical procedure, such as partial or total extirpation of the semilunar cartilage was also noted.*

### Methods

The material was collected by studying the hospital register for the patients admitted during the years 1921—1960. A double control was obtained also by checking the operation register for the same period. All the patient records were produced, and from these summaries were made of the most important details of the case histories, of the entire operation reports and of the postoperative data, and transferred to punched cards. At the follow-up a scheme number 1 (p. 26) was used for the recording of subjective complaints, objective clinical findings, and information on the type of occupation as well as athletic activities after operation. Information whether the patient had had to change to lighter work after the operation, and the reasons for this were also noted. A roentgenologic examination was also made at the follow-up investigation.

#### 1. DATA FROM HOSPITAL RECORDS

*Lockings* were recorded only if data on these occurred in the hospital records; the frequency of the lockings was not noted.

*Effusion* was recorded only if the case records contained the relevant data or if exudate was established and recorded by the examining physician or the surgeon.

*Haemarthrosis* was noted only provided the data were connected with puncture or when operation was performed in close association with trauma.

Because in this hospital the roentgen films are usually discarded after 10 years it was only possible to record the data on *preoperative roentgenologic osteoarthritis* in those cases where information on such changes

When assessing the osteoarthritic signs on the radiographies, the degree of osteoarthritis was indicated by 0, +, ++, or +++, according to the following principles:

Marginal osteophytes:

0 = no signs of accentuation of the condylar margins, on the eminentia, in the fossa intercondyloidea or on the margins of the patella.

1 + = slight accentuation at the above-mentioned places of "Raubert's sign" type.

2 + = a distinct prolongation of the condylar margins or eminentia, in the fossa intercondyloidea or on the margins of the patella.

3 + = advanced osteophytes at the above-mentioned places.

Narrowing of the joint space was assessed by comparing radiographies with and without weight bearing on the knee, and was recorded as 0, if no difference could be demonstrated for certain. If a distinct narrowing of the joint space could be seen when weight bearing, but this was less than half the height of the joint space with the knee unloaded, this was indicated by 1 +. If the difference in the height of the joint space on weight bearing amounted to more than half of that with the knee at rest, but a joint space still existed, this was recorded by 2 +. A complete obliteration of the joint space when standing was recorded by 3 +. A distinct lateral subluxation of the femur in relation to the tibia was specially noted.

The occurrence of flattening of the surface of the femoral condyles was recorded, without any special grading, by +.

The occurrence of sclerosis, especially in the condyles of the tibia, as well as of cystic formations, was recorded, also without any grading, by +.

The roentgenologic findings were transferred only to computer cards.

It must be mentioned here that, in general, when classifying the data obtained from the study of the various parameters examined in this investigation, special care was taken to use classification criteria corresponding as much as possible to those used by the majority of earlier authors.

### 3. STATISTICAL METHODS

For the statistical treatment of obtained differences between 2 or more comparisons the chi-square ( $\chi^2$ ) method was used for testing the probability of differences in frequency of occurrence or non occurrence of the

tion and the squatting position was measured and noted. The test was performed on both the operated and the nonoperated leg. The thigh girth was measured 15 cm above the upper margin of the patella.

Besides these subjective complaints and objective findings, it was recorded whether the patient practised any kind of sport after the operation, and whether, on account of his articular trouble, he had been compelled to change his occupation for work that required less knee strain. When estimating the degree to which the work affected the knee, one had to depend to a great extent on the statements made by the patient himself.

The data on the subjective complaints and the objective findings and on sport and occupation after operation were transferred to a new scheme number 2 (p. 27). In this connection, with regard to the objective findings, the differences between the operated and the nonoperated knee were taken into account. These differences were recorded. Thus, for example, obtained differences in extension-flexion range between the 2 knees were divided into two groups: differences below or at most  $10^{\circ}$ , and differences exceeding  $10^{\circ}$ . The muscular strength of the knee was considered to be reduced if the difference in the ability to rise from the squatting position was greater than  $10^{\circ}$ . Muscular atrophy was regarded as present in the operated leg, and was recorded, if the difference between the thigh girth of the operated and of the nonoperated leg was 2 cm or more. These data were transferred to both punched cards and computer cards.

#### *b. Roentgenologic examination*

At the time of the follow-up investigation both knees were radiologically examined in the Department of Diagnostic Radiology II at the Regional Hospital in Linköping. This examination was made with the patient in both the lying and the standing position with weight bearing on both knees. The importance of radiological examination in the standing position was previously emphasized by Fairbank (1948), and later by Ahlbäck (1968), Bauer (1968) and Bauer & al. (1969) among other authors.

All radiographies were assessed by one and the same senior radiologist, with regard to the reduction of joint space, marginal osteophytes, sclerosis, flattening of the femoral condyle and subluxation. The results were tabulated in accordance with scheme number 3 (p. 27).

In order to exclude any subjective influence on the assessments the radiologist did not know which knee and which semilunar cartilage had been operated on.

Increased skin temperature  
 Soft tissue swelling  
 Hypertrophied "Hoffa"  
 Capsule thickening  
 Effusion

## CHAPTER IV

# Results of follow-up examination of patients with total extirpation of the semilunar cartilage

### 1. ROENTGENOLOGIC RESULTS

#### *Previous investigations*

As shown in table 12 the variation in the frequency of degenerative arthritis after meniscectomy reported by earlier investigators is considerable. These differences may to some extent be due to varying bases of assessment and partly to unequal observation periods in the various materials.

Besides those referred to in table 12 a number of authors have reported frequencies, varying between 8 and 25 per cent without grading the observed signs of degenerative arthritis in detail (Key & Strömberg 1930, Brechling 1942, Lagergren 1953, Saugmann-Jensen 1963, Pelzl & Rueff 1969).

Franke (1966) stated that he was able to show a higher frequency of osteoarthritis in females than in males.

#### *Own observations*

Tables 13 and 14 show the frequency of different signs of osteoarthritis. In classifying the results in these tables, patients operated for a medial

TABLE 12 The frequency of roentgenologic signs of degenerative arthritis according to different authors

semilunar cartilage rupture, with osteophytes present on the medial aspect of the tibia, of degree  $\pm +$  in the operated and  $\pm$  in the nonoperated knee, were placed with regard to osteophytes medially on the tibia, in column 8 in table 13. The observed higher frequency of osteoarthritic signs in the operated than the nonoperated knee is significant as shown in table 15. Thus the roentgenologic signs of osteoarthritis following total extirpation of the semilunar cartilage are significantly higher in the operated than in the nonoperated control knee.

In order to be able to compare the obtained results, in respect of roentgenologically demonstrable degenerative arthritis, with those of other authors, the material has been divided into four groups. In this grouping, following the suggestion of earlier authors (Ahlbäck 1968, Danielsson & Hernborg 1969), more attention has been paid to narrowing of the joint space, flattening of the femoral condyle and sclerosis than to the sum of the osteophytes.

Group 0: this group comprises apparently *normal knees*. (Fig. 4)

Group I: here were allocated knees with radiological signs of *initial osteoarthritis* as slight decrease of the joint space without signs of skeletal changes, other than some minor accentuation of the condylar margins of type 1  $\pm$ . (Fig. 5)

Group II: this contains knees with signs of *pronounced osteoarthritis* such as marked reduction of the joint space with some flattening of the femoral condyle or sclerosis. (Fig. 6)

Group III: here the knees had signs of *severe osteoarthritis* with extensive reduction or total obliteration of the joint space, cystic formations, flattening of the femoral condyles, sclerosis, severe osteophytes and distinct subluxation of the femur in relation to the tibia. As a whole the knees of this group showed signs of extensive osteoarthritic destruction. (Fig. 7)

In view of the difficulties in obtaining a satisfactory evaluation of the radiographies, with necessary requirements of objectivity, when based on the estimations of one person alone, the roentgenograms were evaluated by another senior radiologist as well. He was asked to classify the roentgenologic findings which, according to his opinion, corresponded to the groups of classification referred to above. He obtained no information regarding the results of the first radiologist, and the same measures of security were used to avoid influencing his judgement. The results of the second radiologist were further treated and analysed statistically with regard to the "roentgenologic findings" in the same way as those of the first radiologist. Thus a double control of the estimation of the radiologi-

cal results was achieved. A comparison of the data obtained from both evaluations showed a striking similarity, with only minor divergencies, which will be mentioned separately in the following.

Table 16 shows the number of cases in different groups with regard to the degree of osteoarthritic changes according to the above mentioned criteria. Here it may be pointed out that in 17 patients belonging to group 0 slight signs of degenerative arthritis were found in the nonoperated knee. In group I two patients had more osteoarthritic signs in the nonoperated knee. In groups II and III all the patients had more pronounced signs of degenerative arthritis in the operated knee than in the nonoperated knee. If groups II and III in table 16 are taken together to form one group with distinct osteoarthritic changes in the operated knee, then these cases will amount to only 10.8 per cent<sup>1)</sup> of all the knees subjected to total extirpation of the semilunar cartilage. In 4 among the nonoperated knees, i. e. in 0.9 per cent there were, at the time of the follow-up, roentgenologic signs of degenerative arthritis corresponding to group II and III. In this respect the difference between operated and nonoperated knees is highly significant ( $X^2 = 226.52^{***}$  d. f. = 2). A comparison between laterally and medially meniscectomized knees showed that osteoarthritic changes of groups II and III were present in 8.7 and 11.3 per cent<sup>1)</sup> of the cases respectively. This difference is not significant. When females were compared with males, 19.6 per cent of the former had osteoarthritic changes and 9.6 per cent of the latter<sup>1)</sup>. This difference is almost significant ( $X^2 = 5.81^*$  d. f. = 2).

TABLE 16. Distribution of the totally meniscectomized and nonoperated knees in different groups of roentgenologic osteoarthritis M = males, F = females % = M + F.

Operated meniscus	Total number		Group 0			Group I			Group II			Group III		
	M	F	M	F	%	M	F	%	M	F	%	M	F	%
Medial	327	44	178	16	52.3	116	19	36.4	27	11	8.9	6	3	2.4
Lateral	57	12	32	8	58.0	21	2	33.3	4	2	8.7	0	0	0
Total	384	56	210	24		137	21		31	8		6	3	
	440		234		53.2	158		36.0	39		8.8	6		2.0
Nonoperated	440		427		97.0	9		2.1	3		0.7	1		0.2

<sup>1)</sup> According to the evaluation of the second radiologist (page 29) the frequency of radiologic osteoarthritis was: All total meniscectomized knees 10.2 per cent, medially meniscectomized knees 10.8 per cent, laterally meniscectomized knees 7.2 per cent, for males 9.1 per cent and for females 17.8 per cent.

## *Comments*

If according to Jackson (1968), groups II and I are considered to form together a "normal" group, and groups II and III are combined to form a "degenerative" group, it will be found that both the number and the percentage of knees belonging to the latter group in the present material are lower than in the reports of earlier authors, with the exception of Rothascher (1960) (table 12).

The previously reported occurrence of osteoarthritic changes following total extirpation of the semilunar cartilage was verified and statistically ascertained by the results presented here.

Observed differences between knees operated for rupture of the medial or the lateral semilunar cartilage respectively were not significant. The difference between males and females as regards the frequency of roentgenologic osteoarthritis in the operated knee, was found significant. Thus, earlier statements of a higher frequency of osteoarthritis in females than in males following meniscectomy (Franke 1966) could be verified from the present results.

## a. AGE AT THE TIME OF OPERATION

### *Previous investigations*

The frequency of roentgenologic osteoarthritic changes following meniscectomy has been especially correlated with the patient's age at the time of operation only by a few authors. Varying results have been reported. Thus, it has been stated that by preference patients over 45 years of age should not be subjected to meniscectomy on account of the substantially greater risk of development of osteoarthritis when operating patients of advanced age (Scheide 1963, Herschmann 1965). On the other hand, it has been considered that the patient's age at operation is of no importance for the development of roentgenologic osteoarthritis (Nitter 1946, Saugmann-Jensen 1963).

### *Own observations*

In the entire material of total meniscectomies it was found, on correlating the roentgenologic findings with age at operation, that patients over 41 years had a higher frequency with distinct degenerative arthritis of groups

cal results was achieved. A comparison of the data obtained from both evaluations showed a striking similarity, with only minor divergencies, which will be mentioned separately in the following.

Table 16 shows the number of cases in different groups with regard to the degree of osteoarthritic changes according to the above mentioned criteria. Here it may be pointed out that in 17 patients belonging to group 0 slight signs of degenerative arthritis were found in the nonoperated knee. In group I two patients had more osteoarthritic signs in the nonoperated knee. In groups II and III all the patients had more pronounced signs of degenerative arthritis in the operated knee than in the nonoperated knee. If groups II and III in table 16 are taken together to form one group with distinct osteoarthritic changes in the operated knee, then these cases will amount to only 10.8 per cent<sup>1)</sup> of all the knees subjected to total extirpation of the semilunar cartilage. In 4 among the nonoperated knees, i. e. in 0.9 per cent there were, at the time of the follow-up, roentgenologic signs of degenerative arthritis corresponding to group II and III. In this respect the difference between operated and nonoperated knees is highly significant ( $X^2 = 226.52^{**}$  d. f. = 2). A comparison between laterally and medially meniscectomized knees showed that osteoarthritic changes of groups II and III were present in 8.7 and 11.3 per cent<sup>1)</sup> of the cases respectively. This difference is not significant. When females were compared with males, 19.6 per cent of the former had osteoarthritic changes and 9.6 per cent of the latter.<sup>1)</sup> This difference is almost significant ( $X^2 = 5.81^*$  d. f. = 2).

<sup>1)</sup> According to the evaluation of the second radiologist (page 29) the frequency of radiologic osteoarthritis was: All total meniscectomized knees 10.2 per cent, medially meniscectomized knees 10.8 per cent, laterally meniscectomized knees 7.2 per cent, for males 9.1 per cent and for females 17.8 per cent

## b. LATENCY PERIOD

Correlation of the total results of a follow-up investigation with the time that elapses between an adequate trauma or the onset of the first symptoms and the time of operation — which has been named here the latency period — has been taken up for discussion by several authors. Moreover, the existence of roentgenologic signs of osteoarthritis has also been correlated with the length of the latency period by some authors. A number of investigators have claimed that a clear-cut connection exists between the occurrence of osteoarthritis and a long latency period (Nitter 1946, Barfod & Biering 1956, Scheibe 1963, Mohing 1966, Franke 1966, Gear 1967, Pelzl & Rueff 1969). These statements, however, are not based on statistical verification of the results. On the other hand, it has also been held that no connection exists between higher frequency of degenerative arthritis and a long latency period. (Saugmann-Jensen 1963, Allegreni & Dell'Orto 1965, Jackson 1968, Tapper & Hoover 1969). Among the latter authors only Jackson (1968) and Tapper & Hoover (1969) have

FIG 8 Number of followed-up meniscectomized patients distributed by different groups of roentgenologic osteoarthritis and latency periods. Percentage of osteoarthritic cases given at the top.

II and III than those under 41 (table 17). This difference is almost significant ( $X^2 = 8.80$ , d. f. = 2). The frequency of osteoarthritis was also higher in patients subjected to medial meniscectomy when over 41 than those under 41 years at operation. This difference was also almost significant ( $X^2 = 7.66$ , d. f. = 2). In patients subjected to lateral meniscectomy the frequency of osteoarthritis was found to be higher in subjects over than under 41 years at operation, but this difference is not significant. A comparison was also done for men and women separately. For both males and females analysed separately the frequency of roentgenologic osteoarthritis was higher in cases where a total meniscectomy was performed on patients over 41 years than on those under 41. For men this difference is almost significant ( $X^2 = 6.76$ , d. f. = 2), but not for women.<sup>2)</sup>

### Comments

In this material the frequency of osteoarthritic changes was higher in patients over 41 subjected to total meniscectomy than in those under 41 at the time of operation. The results are in agreement with the findings reported by Scheibe (1963) and Herschmann (1965). The differences were statistically significant for all patients subjected to total meniscectomy, for medial meniscectomies taken separately, as well as for total meniscectomies in males. For laterally meniscectomized knees, and for females examined separately, observed differences were not significant.

TABLE 17 Distribution of the totally meniscectomized knees in different groups of roentgenologic osteoarthritis with regard to age at operation M = males, F = females % = M + F

Operated meniscus	Age at operation	Total		Group 0			Group I			Group II			Group III		
		M	F	M	F	%	M	F	%	M	F	%	M	F	%
Medial	Under 41 years	241	23	140	10	56.8	75	11	32.6	24	2	9.8	2	0	0.8
Lateral	" 41 "	49	7	28	6	60.7	18	0	32.1	3	1	7.2	0	0	0
Total	Under 41 years	290	30	168	16	57.5	93	11	32.5	27	3	9.4	2	0	0.6
Medial	Over 41 years	86	21	38	6	41.2	41	8	45.8	3	4	6.5	4	3	6.5
Lateral	" 41 "	8	5	4	2	46.2	3	2	38.5	1	1	15.3	0	0	0
Total	Over 41 years	94	26	42	8	41.7	44	10	45.0	4	5	7.5	4	3	5.8

<sup>2)</sup> In this respect the results obtained from the evaluation of the roentgenologic findings by the second radiologist (page 29) were divergent. Thus, no significant difference in the frequency of roentgenologic signs of osteoarthritis existed between men operated before or after 41 years of age.

### c. THE TYPE OF TRAUMA

Opinions regarding the importance of the aetiological factor responsible for the rupture of the semilunar cartilage for the occurrence of osteoarthritis diverge widely. It has been stated that trauma as such predisposes to more pronounced osteoarthritis, while the degree of degeneration of the semilunar cartilage is of no importance (Fuss 1951, Tapper & Hoover 1969). On the other hand, there are authors who assert that injuries of the semilunar cartilage without definite trauma are due to increased degeneration of the cartilage and, consequently, of the entire knee. After meniscectomy such a knee is more prone to develop roentgenologic osteoarthritis compared with a healthy knee with traumatic injury of the semilunar cartilage (Rothascher 1960, Franke 1966).

#### *Own investigations*

Among the patients subjected to total meniscectomy 80.9 per cent reported trauma in the history. However, only 30.0 per cent could define the type of trauma, which indicates the difficulty of obtaining reliable information on this matter. These latter patients were divided into different groups according to the type of the main trauma reported, namely in combination with rotation, abduction, adduction or hyperextension of the knee. In 19.1 per cent no certain data regarding the mechanism of the injury were obtainable. Table 18 shows the distribution of the material with regard to traumatic and nontraumatic cases as well as to the type of trauma correlated with the degree of osteoarthritis. The traumatic and

verified their results statistically. Wynn Parry et al. (1958) reported an appreciably higher frequency of osteoarthritic signs at operation in patients with a long latency period.

#### *Own observations*

By dividing the material according to the length of the latency period into 3 different groups, namely, under 1 month, 1—6 months and over 6 months and with a demarcation line at 6 months between a short and a long latency period, a distribution of total meniscectomies is obtained as demonstrated in fig. 8. The lowest frequency of osteoarthritic knees occurs within the latency period of 1—6 months and the highest percentage in the group operated with a maximal latency period of 1 month. These differences in the frequency of osteoarthritis are, however, small and not significant. This applies to all total meniscectomies. Nor were any significant differences observed on comparing separately, medially and laterally meniscectomized knees with the length of the latency period. Totally meniscectomized knees have been tested also for males and females separately with regard to the length of latency period. Existing differences in this respect were not significant. The importance of the latency period for frequency of osteoarthritis was also tested separately for totally meniscectomized knees in patients operated on before and after they were 41 years old respectively. The length of the latency period did not influence the results significantly.

#### *Comments*

Although certain percentage differences were found on correlating the occurrence of osteoarthritis with the length of latency period, these differences were not significant. It can therefore be concluded that the length of the latency period does not play such an important role for the occurrence of osteoarthritis in a meniscectomized knee as has been stated earlier (Nitter 1946, Barfod & Bjerring 1965, Scheibe 1963, Mohing 1966, Franke 1966, Gear 1967, Pelzl & Rueff 1969). The conception that the length of the latency period does not play any part in the occurrence of osteoarthritis in a meniscectomized knee has thus been verified (Saugmann-Jensen 1963, Allegrani & Dell'Orto 1965, Jackson 1968, Tapper & Hoover 1969). It must be pointed out, however, that these observations concern comparisons between short and long latency periods with a borderline at 6 months. It is possible that other correlations would be found if this limit was either increased or decreased.

### c. THE TYPE OF TRAUMA

Opinions regarding the importance of the aetiological factor responsible for the rupture of the semilunar cartilage for the occurrence of osteoarthritis diverge widely. It has been stated that trauma as such predisposes to more pronounced osteoarthritis, while the degree of degeneration of the semilunar cartilage is of no importance (Fuss 1951, Tapper & Hoover 1969). On the other hand, there are authors who assert that injuries of the semilunar cartilage without definite trauma are due to increased degeneration of the cartilage and, consequently, of the entire knee. After meniscectomy such a knee is more prone to develop roentgenologic osteoarthritis compared with a healthy knee with traumatic injury of the semilunar cartilage (Rothascher 1960, Franke 1966).

#### *Own investigations*

Among the patients subjected to total meniscectomy 80.9 per cent reported trauma in the history. However, only 30.0 per cent could define the type of trauma, which indicates the difficulty of obtaining reliable information on this matter. These latter patients were divided into different groups according to the type of the main trauma reported, namely in combination with rotation, abduction, adduction or hyperextension of the knee. In 19.1 per cent no certain data regarding the mechanism of the injury were obtainable. Table 18 shows the distribution of the material with regard to traumatic and nontraumatic cases as well as to the type of trauma correlated with the degree of osteoarthritis. The traumatic and

nontraumatic cases correlated with the degree of degenerative arthritis are given in fig. 9. Only slight, not significant differences in the frequency of osteoarthritis were found on comparing total meniscectomies in traumatic and nontraumatic cases.

### Comments

With regard to the frequency of osteoarthritis no significant difference existed between knees where rupture of the semilunar cartilage was due to trauma or not. This verifies the conception that trauma is not import-

FIG 9 Number of followed-up meniscectomized patients distributed by different groups of roentgenologic osteoarthritis and factor trauma Percentage of osteoarthritic cases given at the top.

ant for the occurrence of osteoarthritis after meniscectomy (Rothascher 1960, Franke 1966). On the other hand, it may also be said that the obtained results do not support the opinion of the above-mentioned authors, that rupture of the semilunar cartilage without trauma causes a higher frequency of roentgenologic osteoarthritis in the meniscectomized knee, because of generalized degenerative changes of the joint.

#### d. OBSERVATION PERIOD

Many authors consider that the length of the observation period is of importance for the occurrence of degenerative arthritis in a meniscectomized knee. They maintain, therefore, that an observation period of at least 15—20 years is required for a material to be considered representative (Nitter 1946, Sireli 1955, Saugmann-Jensen 1963, Allegreni & Dell'Orto 1965, Mohing 1966, Jackson 1968). Other authors consider that there is no connection between the frequency of osteoarthritis and a long observation period (Brechtling 1942, Fuss 1951, Barlod & Biering 1956, Tapper & Hoover 1969).

##### *Own investigations*

As has been previously stated, the observation period has been divided into 10-year periods. The largest number of cases was found in the observation period 4—13 years. In the entire material there was a higher frequency of radiologic signs of degenerative arthritis of groups II and III in patients with an observation period over 24 years than for those with one under 24 years (table 19). The increase in the frequency of osteo-

TABLE 19 Distribution of totally meniscectomized knees in the different groups of roentgenologic osteoarthritis with regard to the observation period in decades M = males, F = females % = M + F

nontraumatic cases correlated with the degree of degenerative arthritis are given in fig. 9. Only slight, not significant differences in the frequency of osteoarthritis were found on comparing total meniscectomies in traumatic and nontraumatic cases.

### Comments

With regard to the frequency of osteoarthritis no significant difference existed between knees where rupture of the semilunar cartilage was due to trauma or not. This verifies the conception that trauma is not import-

FIG. ■ Number of followed-up meniscectomized patients distributed by different groups of roentgenologic osteoarthritis and factor trauma. Percentage of osteoarthritic cases given at the top.

tive with regard to the roentgenologic signs of osteoarthritis (Nitter 1946, Streli 1955, Saugmann-Jensen 1963, Allegreni & Dell-Orto 1965, Mohing 1966, Jackson 1968).

Moreover, it is obvious from the studies of the nonoperated knee mentioned above, that the higher frequency of roentgenologic osteoarthritis with increasing time of observation does not only depend on the increasing age of the patient. Thus, it has been observed that the frequency of osteoarthritis was significantly higher in the operated than the nonoperated knee in all the groups of observation period.

#### e. OTHER FACTORS THAT POSSIBLY PROMOTE OCCURRENCE OF OSTEOARTHRITIS

Besides the factors already analyzed there may be others too which possibly can contribute to the occurrence of roentgenologic osteoarthritis following meniscectomy. The results of other analyzed factors will be presented here.

*Clinical findings prior to operation*, such as effusion, lockings, haemarthrosis or a combination of these occurred in 352 of the 440 cases or 80.4 per cent of total meniscectomies, distinctly more in the medially than in the laterally meniscectomized knees. No significant difference could be established in the frequency of osteoarthritis with regard to the presence or absence of preoperative clinical findings.

As has been previously stated, *roentgenologic signs of degenerative arthritis prior to operation* could be recorded only by means of the radiological reports. It was only in 36 out of 440 cases of totally meniscectomized knees that osteoarthritis had been reported. The frequency of degenerative arthritis at the follow-up investigation was significantly higher in patients with preoperative roentgenologic osteoarthritis than in those without ( $X^2 = 36.41^{***}$  d. f. = 3). Among the 36 cases with preoperative roentgenologically demonstrable degenerative arthritis there were 9 knees which did not show any roentgenologic osteoarthritis at the follow up examination, these knees were regarded as belonging to group 0. This finding is in agreement with similar observations reported by Meier (1933) and Pelzl & Rueff (1969). A possible explanation of this regression of osteoarthritic changes may be, that a disturbing agent had been removed from the joint by meniscectomy.

arthritis for an observation period over 24 years is almost significant ( $X^2 = 14.4^*$  d. f. = 6). For medially meniscectomized patients taken separately, there is also a significant increase in the frequency of osteoarthritis when the observation period exceeded 24 years ( $X^2 = 9.5^*$  d. f. = 4). On the contrary, laterally meniscectomized knees do not show any significant differences in the frequency of osteoarthritis in relation to the length of the observation period. When correlating frequency of degenerative arthritis with length of the observation period for males and females separately, the males were found to have increased frequency when the observation period exceeded 24 years. The difference was significant ( $X^2 = 13.39^{**}$  d. f. = 4). For the females no significant differences were observed.

TABLE 19 a. *Distribution of nonoperated knees in the different groups of roentgenologic osteoarthritis with regard to the observation period in decades. M = males, F = females. % = M + F.*

Observation period	Total		Group 0			Group I			Group II			Group III		
	Number		Number		%	Number		%	Number		%	Number		%
	M	F	M	F		M	F		M	F		M	F	
4—13 years	219	44	216	42	98.1	3	2	19	0	0	0	0	0	0
14—23 "	106	8	104	6	96.5	2	0	17	0	1	09	0	1	09
24—43 "	59	4	55	4	93.6	2	0	32	2	0	32	0	0	0
Total	384	56	375	52		7	2		2	1		0	1	

As shown in table 19 a, increased frequency of degenerative arthritis occurs also in the nonoperated knee with the increase of time between the operation of the other knee and the follow-up examination. There was, further, a significantly higher frequency of osteoarthritis in the operated as compared with the nonoperated knee increasing with the period of observation, i. e. in the 4—13 years group ( $X^2 = 134.04^{***}$  d. f. = 2); in the 14—23 years group ( $X^2 = 54.92^{***}$  d. f. = 2); and in the 24—43 years group ( $X^2 = 34.92^{**}$  d. f. = 2).

### Comments

The results of this investigation show a significant increase in the frequency of roentgenologic signs of osteoarthritis for observation periods exceeding 24 years compared with those under 24 years. Thus, these results support the opinion that a material consisting of meniscectomized knees should have a sufficiently long observation period to be representa-

nive with regard to the roentgenologic signs of osteoarthritis (Nitter 1946, Streli 1955, Saugmann-Jensen 1963, Allegreni & Dell-Orto 1965, Mohing 1966, Jackson 1968).

Moreover, it is obvious from the studies of the nonoperated knee mentioned above, that the higher frequency of roentgenologic osteoarthritis with increasing time of observation does not only depend on the increasing age of the patient. Thus, it has been observed that the frequency of osteoarthritis was significantly higher in the operated than the nonoperated knee in all the groups of observation period.

#### e. OTHER FACTORS THAT POSSIBLY PROMOTE OCCURRENCE OF OSTEOARTHRITIS

Besides the factors already analyzed there may be others too which possibly can contribute to the occurrence of roentgenologic osteoarthritis following meniscectomy. The results of other analyzed factors will be presented here.

*Clinical findings prior to operation*, such as effusion, lockings, haemarthrosis or a combination of these occurred in 352 of the 440 cases or 80.4 per cent of total meniscectomies, distinctly more in the medially than in the laterally meniscectomized knees. No significant difference could be established in the frequency of osteoarthritis with regard to the presence or absence of preoperative clinical findings.

As has been previously stated, *roentgenologic signs of degenerative arthritis prior to operation* could be recorded only by means of the radiological reports. It was only in 36 out of 440 cases of totally meniscectomized knees that osteoarthritis had been reported. The frequency of degenerative arthritis at the follow-up investigation was significantly higher in patients with preoperative roentgenologic osteoarthritis than in those without ( $X^2 = 36.41^{***}$  d. f. = 3). Among the 36 cases with preoperative roentgenologically demonstrable degenerative arthritis there were 9 knees which did not show any roentgenologic osteoarthritis at the follow up examination, these knees were regarded as belonging to group 0. This finding is in agreement with similar observations reported by Meier (1933) and Pelzl & Rueff (1969). A possible explanation of this regression of osteoarthritic changes may be, that a disturbing agent had been removed from the joint by meniscectomy.

*Osteoarthritis and other secondary findings at operation* were only described in the hospital records in a comparatively few cases (table 20). Statistical analysis of the effect of other secondary findings on the development of roentgenologic osteoarthritis after the operation was therefore not possible. Description of degenerative changes observed in the joint at the time of operation was, however, frequent and analysis with respect to this finding became possible.

The frequency of roentgenologic osteoarthritis was higher at the follow-up investigation in those patients who at operation had had demonstrable osteoarthritis compared with the patients without signs of it. The difference was highly significant ( $X^2 = 24.04^{***}$  d. f. = 3). Here, it is also noteworthy that in 12 patients with osteoarthritis at operation, no signs of such a condition were found in radiographies taken at the follow-up examination.

TABLE 20. *Distribution of totally meniscectomized knees in the different groups of roentgenologic osteoarthritis with regard to the various operative findings. M = males, F = females.*

Operative findings	Group 0		Group I		Group II		Group III	
	Number		Number		Number		Number	
	M	F	M	F	M	F	M	F
Injuries of coll. lig.	2	0	1	1	0	0	0	0
" " cruc. "	3	0	2	0	0	0	0	0
Chondrom. patellae	1	1	5	1	2	0	1	0
Osteochondr. dissec.	2	0	4	0	1	1	1	0
Osteoarthritis	11	1	12	6	6	2	3	1

*Signs of infection after operation* were recorded in 21 cases (4.8 per cent). One of these cases was allocated to group II and another to group III. *Effusion* persisting longer than 3 weeks postoperatively was noted in the hospital records in 15 cases; none of these cases belonged to group III and only one in group II. *Haemarthrosis* was recorded in 20 cases, with one case in group II and none in group III. The frequency of osteoarthritis at the follow-up investigation did not show any significant differences between patients with and without such postoperative complications.

According to the hospital records *muscular training* had been applied postoperatively in 199 cases or in 45.2 per cent of the total meniscectomies. The frequency of roentgenologic signs of osteoarthritis at the follow-

up investigation in patients who had had muscular training compared with those where data on such training were lacking, did not show any significant difference.

*Splint fixation* was applied in 167 cases and fixation by a plaster cast only in 4 operated patients. The frequency of degenerative arthritis was higher in patients with postoperative fixation than in those without fixation. The difference is almost significant ( $X^2 = 10.8^*$  d. f. = 3).<sup>3)</sup>

Patients who were *allowed to bear weight* on the operated leg first after the 2nd postoperative week had a higher frequency of osteoarthritic changes than those where weight bearing was allowed earlier. (Table 21). This difference is also almost significant ( $X^2 = 10.07^*$  d. f. = 4).<sup>4)</sup> This finding together with the observation that postoperative complications did not significantly affect the occurrence of osteoarthritis may indicate partly that restriction with weight bearing was probably due to different principles of treatment (Pelzl & Rueff 1969), and partly that early weight bearing does not promote the occurrence of osteoarthritis.

TABLE 21 *Distribution of totally meniscectomized knees in the different groups of roentgenologic osteoarthritis in respect of the time when weight bearing was allowed postoperatively M = males, F = females % = M + F.*

Postop weight bearing	Total Number		Group 0				Group I				Group II				Group III			
			Number		%		Number		%		Number		%		Number		%	
	M	F	M	F			M	F			M	F			M	F		
Within 1 week	40	2	21	2	54.8	111	0	42.8	1	0	24	0	0	0				
" 8-14 days	258	31	150	14	56.7	82	13	32.9	22	4	90	4	0	14				
After 2 weeks	86	23	39	8	43.1	37	8	41.3	8	4	110	2	3	46				
Total	384	56	210	24		137	21		31	8					6	3		

Short or long *duration of postoperative hospitalization* did not show any significant difference when correlated with the frequency of osteoarthritis.

141 persons had had *athletic activities after operation*, or 32.0 per cent of the totally meniscectomized patients. None of these cases belonged to group III, and only 4 to group II. That postoperative sport could have a prophylactic effect on the occurrence of *osteoarthritis* is improbable; it

<sup>3-4)</sup> The results obtained from the analysis of the roentgenologic findings based on the evaluation of the second radiologist showed no significant difference in the frequency of roentgenologic signs of osteoarthritis between a) patients treated with or without postoperative fixation, and b) patients who were allowed weight bearing earlier or later than 2 weeks

is more likely that patients with degenerative arthritis refrained from sport after the operation. Scheibe (1963) pointed out, however, that athletic activities after operation do not appear to increase the frequency of osteoarthritis in meniscectomized knees.

The *type of occupation engaged in after operation* might conceivably be of importance for the occurrence of roentgenologic arthritis; work causing more knee strain would be liable to result in a higher frequency of osteoarthritis. On the whole, however, there is no significant difference between the various occupational groups in this material with regard to the frequency of degenerative arthritis.

According to Aarstrand (1954), the mean age of patients with roentgenologic signs of osteoarthritis at the follow-up examination was higher than that of patients without such findings.

As shown in table 22 the highest frequency of osteoarthritis occurred among patients who were at least 61 years old at the time of the follow-up investigation. The difference in the frequency of osteoarthritis compared with that of age groups under 61 at the follow-up is highly significant ( $X^2 = 19.24^{***}$  d. f. = 4). If, besides *age at the follow-up investigation* also the length of the observation period is taken into consideration, the same high frequency of osteoarthritis will be found for patients over 61 years old and with a short observation period between 4—13 years. This difference is also highly significant ( $X^2 = 19.45^{***}$  d. f. = 4). The significantly higher frequency of osteoarthritis in the oldest group of followed-up patients appears to be connected with the demonstrated higher frequency of degenerative arthritis for patients operated after 41 years of age.

A comparison has also been made between the operated and the non-operated knee in respect of the frequency of degenerative arthritis in the

TABLE 22 *Distribution of totally meniscectomized knees in the different groups of roentgenologic osteoarthritis in respect of the patient's age at the follow-up*

various age groups at the follow-up. A significantly higher frequency of osteoarthritis is found in the operated knee in all age groups; in the age group under 41 years ( $X^2 = 60.86^{***}$  d. f. = 2), in the group 41–60 years ( $X^2 = 124.43^{***}$  d. f. = 2) and in the group over 61 years ( $X^2 = 46.08^{***}$  d. f. = 2).

## f. SUMMARY OF ROENTGENOLOGIC RESULTS

Roentgenologic osteoarthritis following meniscectomy has proved to be significantly more frequent in the operated knee than in the nonoperated knee.

On the whole it has not been possible to establish any significant difference between medially and laterally meniscectomized knees. In agreement with Franke (1966) a significantly higher frequency of roentgenologic osteoarthritis was found in this material too in women as compared with men.

Scheibe (1963) and Herschmann (1965) among others consider that preferably patients over 40–45 years should not be operated, because of the risk of osteoarthritis, developing in the operated knee as a result of the intervention, being greater in older patients than in younger. In this material it was also found that the frequency of osteoarthritis was higher in the operated knees of patients meniscectomized when they were over 41 years old compared with those operated before they were 41. The differences are almost significant for total meniscectomies in the entire material ( $X^2 = *$ ), for medially meniscectomized knees ( $X^2 = *$ ), and for men ( $X^2 = *$ )<sup>1)</sup> The differences for laterally meniscectomized knees and for women were not statistically significant.

It has been maintained that a long latency period causes an increase in the frequency of degenerative arthritis in a meniscectomized knee (Nitter 1946, Barfoed & Biering 1956, Scheibe 1963, Franke 1966, Mohing 1966). This material has not shown any significant connection between a longer latency period and a higher frequency of osteoarthritis in the meniscectomized knees; this is in agreement with the observations of other authors (Saugmann-Jensen 1963, Allegretti & Dell'Orto 1965, Jackson 1968, Tapner & Hoover 1969)

<sup>1)</sup> see footnote page 32

The importance of an initial trauma for the development of degenerative arthritis following meniscectomy has been pointed out earlier (Fuss 1951, Tapper & Hoover 1969). In the present material no statistically significant difference has been found, between the patients operated for traumatic and nontraumatic injuries of the semilunar cartilage, with regard to the frequency of roentgenologic osteoarthritis in the meniscectomized knee.

It has been asserted that the length of the observation period is of importance for the frequency of roentgenologic osteoarthritis. Consequently several authors have pointed out that a material can be regarded as representative only if the observation period is sufficiently long (Nitter 1946, Stréli 1955, Saugmann-Jensen 1963, Allegreni & Dell'Orto 1965, Mohing 1966, Jackson 1968). In this material an increasing frequency of degenerative arthritis has been found for longer observation periods than 24 years compared with shorter. In this respect the obtained differences are almost significant for the entire material of total meniscectomies ( $X^2 = *$ ), for medially meniscectomized knees alone ( $X^2 = *$ ), and highly significant for men alone ( $X^2 = ***$ ).

Among other factors which possibly provoke osteoarthritis, preoperative symptoms — lockings, effusion, haemarthrosis or a combination of these — and postoperative complications have not been found to affect the frequency of roentgenologic osteoarthritis in a significant way. Correlation of the frequency of roentgenologic osteoarthritis with postoperative muscular training, duration of hospitalization, sport after operation, or effect on the knee of type of occupation did not give significant differences. On the other hand, a significantly higher frequency of degenerative arthritis at the follow-up examination was found in knees in which roentgenologic signs of osteoarthritis existed already prior to operation ( $X^2 = ***$ ), if osteoarthritis was diagnosed at operation ( $X^2 = ***$ ), if fixation was applied postoperatively ( $X^2 = *$ )<sup>6</sup>, when weight bearing on the operated knee was allowed first after 2 weeks ( $X^2 = *$ )<sup>7</sup>, and in patients of advanced age at the follow-up investigation in spite of shorter observation periods ( $X^2 = ***$ ). Also by comparing the operated and the non-operated knee a higher degree of osteoarthritis was found in patients of advanced age at follow-up as compared with younger patients ( $X^2 = **$ ).

<sup>6-7</sup>) see footnote page 41

## 2. SUBJECTIVE COMPLAINTS

The reported frequency of different subjective complaints varies largely according to different authors (table 23). These variations are probably due to the different methods applied in collecting data. Some authors base their conclusions solely on answers to questionnaires sent to the subject (Strahlmann & White 1921, MacAusland 1931, Meier 1933, Sjövall 1942, Perey 1962). Other authors rely their reports partly on questionnaires and partly on interrogation at personal investigations (Lagergren 1953, Kühnel 1964, Huckell 1965). Some authors base their results exclusively on interrogation at the follow-up investigation (Birgfeld 1928, Aleman & Friberg 1934, Saugmann-Jensen 1963, Franke 1966).

Franke (1966) stated that 75.2 per cent of the patients with roentgenologic changes were subjectively entirely free from symptoms. Jackson (1968) also pointed out that there was not always agreement between roentgenologic signs of degenerative arthritis and subjective complaints.

Sjövall (1942) reported that in his material 44 per cent of the patients complained of weakness in the operated knee.

TABLE 23 *The frequency of subjective complaints in different groups according to different authors*

Authors	Number of cases	Excellent %	Good %	Fair %	Bad %
Strahlman & White (1921)	50		86.0		14.0
Birgfeld (1928)	68	79.4	16.2	2.9	1.5
MacAusland (1931)	287	80.1	9.8	10.1	
Meier (1933)	146	68.5	31.5	0	0
Aleman & Friberg (1934)	186	85.5			
Sjövall (1942)	140	20.1	51.4	26.4	2.1
Lagergren (1953)	97	64.0	21.0	10.0	5.0
Perey (1962)	33	70.0	15.0		
Saugmann-Jensen (1965)	93	61.3	25.8	7.5	5.4
Monn (1964)	52	56.0	19.0		
Kühnel (1964)	326	79.8	15.3	25.0	
Huckell (1965)	64	40.0	24.0	4.9	
Franke (1966)	98	41.9	36.7	20.0	16.0
Appel (1970)	440	62.3	29.1	16.3	5.1
				7.5	1.1

### *Own investigations*

As was mentioned in the chapter on Methods, a standardized form was used to record subjective complaints reported by the patient. The frequency of these complaints, regardless of their degree, is shown in table 24. The two most frequent complaints were pain on weight bearing and a feeling of weakness in the knee. The frequency of pain on weight bearing was significantly higher in females ( $X^2 = 21.39^{***}$  d. f. = 1) than in males. There was no significant difference between medially operated and laterally operated knees with regard to pain on weight bearing.

TABLE 24. *The frequency of different subjective complaints in patients after total meniscectomy.*

Subjective complaints	Medial		Lateral	
	Males	Females	Males	Females
Pain at rest	14	5	2	2
Pain on weight bearing	66	22	16	6
Weakness feeling	63	15	16	3
Walking disability	32	14	7	0
Lockings	3	3	2	0
Other complaints	15	1	5	0

Feeling of weakness in the operated knee did not show any significant difference between medially and laterally operated knees, nor when men and women were compared in this respect.

Difficulty in going upstairs or uphill occurred also comparatively often and the frequency was significantly higher for women than for men ( $X^2 = 10.16^{**}$  d. f. = 1). No significant difference was established between medially and laterally meniscectomized knees.

Each patient might have no complaints or some or all of those included in the form. Each individual complaint was graded with symbols 1+, 2+ or 3+ according to the intensity mentioned by the patient. Thus, for example, a patient could complain of moderate pains on weight bearing (1+) and pronounced difficulty in going upstairs (2+) and at the same time also slight swelling (1+). This patient was given a *total grading* of 4+. Another patient complained, for example, of mild pain on weight bearing (1+) and moderate feeling of weakness in the knee (1+) and was given a *total* of 2+. A patient was placed with regard to the total score of + he acquired, in one of the four groups for subjective complaints i. e., *Excellent*: symptom-free; *Good*: 1+ or 2+; *Fair* 3+ or

4+ and Bad: 5+ or more. However a few patients stating several complaints of slight degree, were allocated to either group Good or Fair according to the general impression given by the described intensity of their combined complaints.

In respect of subjective complaint, the material consisting of total meniscectomies was divided according to the above principles, as shown in table 25.

TABLE 25 *Distribution of totally meniscectomized knees in different groups of subjective complaints M = males, F = females % = M + F*

Operated meniscus	Total number		Excellent			Good			Fair			Bad		
	M	F	M	F	%	M	F	%	M	F	%	M	F	%
Medial	327	44	219	18	63.9	88	15	27.7	16	10	7.0	4	1	1.4
Lateral	57	12	32	5	53.6	18	7	36.3	7	0	10.1	0	0	0
Total	384	56	251	23	62.3	106	22	29.1	23	10	7.5	4	1	1.1

If subjective complaints are correlated with the roentgenologic findings it is obvious that there is not always an agreement between them (table 26).

TABLE 26 *Distribution of totally meniscectomized knees in different groups of subjective complaints correlated with the distribution by different roentgenologic groups of osteoarthritis M = males, F = females*

Roentgenologic findings	Total		Subjective complaints							
	M	F	Excellent		Good		Fair		Bad	
	M	F	M	F	M	F	M	F	M	F
Group 0	210	24	152	9	50	11	8	4	0	0
Group I	137	21	89	10	38	8	10	3	0	0
Group II	31	8	10	3	14	3	4	1	3	1
Group III	6	3	0	1	4	0	1	2	1	0
Total	384	56	251	23	106	22	23	10	4	1

If the occurrence of clear-cut subjective complaints of group Fair and group Bad is compared between women and men, the total subjective complaints show a significantly higher frequency for women ( $X^2 = 15.92^{***}$  d. f. = 2). On the other hand, there is no significant difference between medially and laterally meniscectomized knees.

## Comments

The present material shows a lower frequency of cases with clear-cut subjective complaints of groups Fair and Bad compared with the reports of other authors (table 23). Aleman & Friberg (1934) reported higher frequency of *Excellent* and *Good* results, without giving an account, however, of their bad results. Perey (1962) had a lower percentage of cases belonging to groups *Excellent* and *Good* and MacAusland (1931) a higher percentage belonging to groups *Fair* and *Bad*.

The present material shows a significantly higher frequency of subjective complaints for women than for men. There were no significant differences between medially and laterally meniscectomized knees.

As was also reported by Franke (1966) and Jackson (1968) in many cases here the degree of roentgenologic findings of osteoarthritis and the subjective complaints were not always in agreement.

In order to shed more light on the effect of the different factors on the subjective complaints, this has been analyzed in the same way as the roentgenologic findings.

### a. AGE AT TIME OF OPERATION

Earlier reports maintain that the frequency of subjective complaints following meniscectomy is lower in younger than in older patients (Mac Ausland 1931, Saugmann-Jensen 1963). Lower frequency of subjective complaints has also been reported for elderly patients at the time of operation (Meier 1933). Some authors have maintained that nothing definite can be stated concerning the importance of age at operation for the occurrence of subjective complaints (Lagergren 1953, Monn 1964, Huckell 1965).

#### *Own investigations*

When the subjective complaints in this material are correlated with age at operation, for patients over and under 41 years, there are only small differences in the frequency of subjective complaints (table 27). These differences are not statistically significant.

## Comments

Correlation between subjective complaints and age at operation does not show in the present material any statistically significant differences as regards the frequency for subjective complaints of the groups *Fair* and *Bad* in patients operated either before or after 41 years of age. These results point in the same direction as the results of several other authors, who consider that age at operation is of no importance for the occurrence of subjective complaints (Lagergren 1953, Monn 1964, Huckell 1965).

TABLE 27 Distribution of totally meniscectomized knees in different groups of subjective complaints correlated with age at operation. M = male, F = females % = M + F

Age at operation	Total		Excellent		%	Good		%	Fair		%	Bad		%
	Number		Number			Number			Number					
	M	F	M	F		M	F		M	F		M	F

Under 41 years	290	30	190	10	62.5	79	16	29.7	18	3	6.6	3	1	1.2
41-50 years	60	17	39	9		19	3		2	5		0	0	
51-60     "	32	8	21	4		7	2		3	2		1	0	
Over 61   "	2	1	1	0		1	1		0	0		0	0	
Over 41 years	94	26	61	13	61.7	27	6	27.5	5	7	10.0	1	0	0.8

## b. LATENCY PERIOD

Several earlier authors consider the risk of increased frequency of subjective complaints following meniscectomy to be greater with longer latency period and, consequently, they recommend that operation should be performed as early as possible (Strahlman & White 1921, Birgfeld 1928, MacAusland 1931, Saugmann-Jensen 1963, Kuhnel 1964, Huckell 1965). However, there are also authors who did not observe any correlation between subjective complaints and long latency period (Sjovall 1942, Monn 1964).

# Own investigations

Table 28 and fig. 10 show the distribution of the material when subjective complaints are correlated with latency periods shorter and longer than 6 months. In total meniscectomies a higher frequency of knees, causing subjective complaints of the groups *Fair* and *Bad*, was observed among patients who were operated with a latency period of less than 6 months compared with knees operated after 6 months, but the difference is not statistically significant. No significant differences in the frequency of subjective complaints in respect of the latency period were observed for either medially or laterally meniscectomized knees or separately for men and women.

Nor has the length of the latency period any effect on the subjective complaints when correlating these with latency periods longer or shorter than 6 months in patients under or over 41 years at the time of operation.

## Comments

In the present material no statistically significant differences in the frequency of subjective complaints were established for knees operated after latency periods longer or shorter than 6 months. These results are thus in agreement with the view that the length of the latency period is of no importance for the occurrence of subjective complaints (Sjovall 1942, Monn 1964).

TABLE 28 *Distribution of totally meniscectomized knees in different groups of subjective complaints correlated with the latency period M = males, F = females. % = M + F*

Operated meniscus	Latency period	Total Number		Excellent			Good			Fair			Bad		
		M	F	M	F	%	M	F	%	M	F	%	M	F	%

FIG 10 Percentage of followed-up meniscectomized patients distributed by different groups of subjective complaints and latency periods. Percentage of groups Fair and Bad given together at the top

### c. TYPE OF TRAUMA

There are only a few authors who correlate the type of trauma or its absence with subjective complaints alone. It may be mentioned, however, that MacAusland (1931) stated that even slight traumata are important for the degree of subjective complaints after meniscectomy, while Tapper & Hoover (1969) consider that a more pronounced trauma may be the cause of increased subjective complaints.

#### *Own investigations*

When the total meniscectomies are divided into definitely traumatic and nontraumatic cases, and these two groups are then correlated with the

different groups of subjective complaints, the distribution shown in table 29 is obtained. Investigation of the relation between traumatic and non-traumatic injuries of the semilunar cartilage and the frequency of subjective complaints of the groups *Fair* and *Bad* after meniscectomy did not shows any significant differences.

### Comments

In the present material there was no significant difference with regard to the subjective complaints, between knees meniscectomized because of traumatic and nontraumatic injuries of the semilunar cartilage respectively. This conflicts with the view held by other authors (MacAusland 1931, Tapper & Hoover 1969).

TABLE 29. Distribution of totally meniscectomized knees in different groups of subjective complaints correlated with the factor trauma.  
M = males, F = females. % = M + F

Total	384	56	251	23		106	22		23	10		4	1	

#### d. OBSERVATION PERIOD

Unanimity in assessing the importance of the length of the observation period in relation to subjective complaints is striking. No author has reported an increase in subjective complaints after a longer observation period. Most authors do not report any difference in this respect between cases with longer and shorter observation periods (Meier 1933, Sjøvall 1942, Perey 1962, Tapper & Hoover 1969), while a decrease in subjective complaints after a longer observation period has also been reported (Monn 1964).

FIG 1) Percentage frequencies of the different groups of subjective complaints according to observation period in decades

### *Own investigations*

Table 30 shows the subjective complaints after meniscectomy correlated with the observation time divided into 10-years periods. The frequency of subjective complaints of groups *Fair* and *Bad* decreased slightly with increasing observation periods (fig. 11). The differences are not significant.

### *Comments*

In contrast to ■ significantly increased frequency of roentgenologic signs of osteoarthritis with an increasing observation period, there was a slight, though not significant decrease in the frequency of subjective complaints of groups *Fair* and *Bad*. This is in agreement with the conception of other authors regarding the influence of the observation period on subjective complaints (Meier 1933, Sjövall 1943, Percy 1962, Tapper & Hoover 1969).

## e. OTHER FACTORS WHICH POSSIBLY PROVOKE SUBJECTIVE COMPLAINTS

A comparison between meniscectomized knees with and without *pre-operative clinical findings*, such as lockings, effusion etc. did not show any significant differences in respect of subjective complaints.

When comparing meniscectomized knees with and without *osteoarthritis diagnosed prior to or at operation*, there was no significant difference as regards the frequency of subjective complaints at the follow-up. *Other findings at operation*, such as osteochondritis, ligament injuries etc. occurred in so few cases that no analysis of these was possible.

No *postoperative complications* had occurred in any of the patients belonging to the group *Bad*. Nor did any patient in the group *Fair* display postoperative infection; but in this group there had been three cases of persisting effusion and two patients had had haemarthrosis. No statistically significant differences were observed in the frequencies of the subjective complaints when comparing knees separately with and without either of these postoperative complications after meniscectomy.

Meniscectomized knees in patients with and without *postoperative muscular training* did not show any significant differences on correlation with frequency of subjective complaints of groups *Fair* and *Bad*. The same applies also when comparing operated knees with and without *postoperative fixation*.

Meniscectomized knees where *weight bearing* was allowed first 2 weeks postoperatively showed an almost significant higher frequency of subjective complaints, when compared with knees where weight bearing was allowed earlier ( $X^2 = 10.08^*$  d. f. = 4) (table 31).

Patients hospitalized for longer than 2 weeks after the operation showed a higher frequency of subjective complaints compared with those with a shorter *hospitalization* ( $X^2 = 6.36^*$  d. f. = 2) (table 32).

No patient in the group *Bad* had practised any kind of sport after operation; only five in the group *Fair* had done so.

The *type of occupation after operation* had no significant influence on the frequency of subjective complaints.

With regard to the subjective complaints, *age at the follow-up investigation* does not seem to play the same role as for the roentgenologic findings. No significant differences were found between various age groups when these were correlated with the degree of subjective complaints.

TABLE 31 Distribution of totally meniscectomized knees in different groups of subjective complaints correlated with the time when weight bearing was first allowed after operation M = males, F = females. % = M + F.

Total	384	56	251	23		106	22		23	10		4	1	

## f. SUMMARY OF SUBJECTIVE COMPLAINTS

On the whole, subjective complaints observed in the present material were of the same order of size as that reported by earlier authors (MacAusland 1931, Aleman & Friberg 1934, Percy 1962).

In several respects women were found to have a higher frequency of subjective complaints than men ( $X^2 = **$  to  $***$ ).

Lower frequencies of subjective complaints for patients who were younger at operation had been reported earlier (MacAusland 1931, Saugmann-Jensen 1963). This conception has not been verified in this material. Thus, with regard to subjective complaints, no significant differences between patients operated before or after 41 year of age were found. This supports the view that the age at the time of operation does not influence the occurrence of subjective complaints (Lagergren 1953, Monn 1964, Huckell 1965).

The length of the latency period has not been found to influence significantly the frequency of subjective complaints. This corresponds with the statements of Sjövall (1942) and Monn (1964) among other investigators.

Trauma or its absence in connection with injury of the semilunar cartilage could not be significantly linked with the occurrence of subjective complaints after operation. This observation disagrees with the assertion made by MacAusland (1931) and Tapper & Hoover (1969), that an initial trauma gives rise to higher frequency of subjective complaints following meniscectomy.

The frequency of subjective complaints with regard to the length of the observation period showed no significant differences, which corresponds with earlier reported observations. (Meier 1933, Sjövall 1942, Percy 1962, Tapper & Hoover 1969).

Weight bearing at a later stage after the operation and longer hospitalization time have shown a significantly higher frequency of subjective complaints ( $X^2 = *$ ).

### 3. OBJECTIVE CLINICAL FINDINGS

In reports concerning follow-up investigations of meniscectomized patients, thorough analysis of registered objective symptoms, such as decreased range of motion, loss of strength, and muscular atrophy is more or less neglected. Subjective complaints are sometime added to descriptions of the local status as reported by the patient in follow-up investigations based on questionnaires, or objective findings, subjective complaints and roentgenologic findings are all added together in the evaluation of the results of follow-up investigations performed personally by the author. Normal findings in respect especially of objective symptoms have been reported to vary between 40 and 70 per cent (Efskind 1939, Saugmann-Jensen 1963).

#### *Own investigations*

As stated in the chapter on "Methods", the objective symptoms observed at the follow-up examination were recorded on the standardized scheme 1 and the results of the comparison of the findings between the operated and the nonoperated knee were transferred to scheme 2. The frequency of the various objective symptoms is demonstrated in table 33. In this connection it should be pointed out that several objective symptoms may have been observed in the same patient.

TABLE 33 The frequency of various objective findings at the follow-up in totally meniscectomized patients The operated knee is compared with the non-operated

	Medial		Lateral		Total	%
	Males	Females	Males	Females		
Decreased range of active extension (up to 10°)	8	4	1	0	13	2.9
Decreased range of active extension (more than 10°)	0	0	0	1	1	
Decreased range of active flexion (up to 10°)	20	3	7	1	31	7.0
Decreased range of active flexion (more than 10°)	9	6	6	0	21	4.8
Decreased muscular strength (more than 10°)	39	6	10	2	57	12.9
Quadriceps atrophy (more than 2 cm)	8	1	2	0	11	2.5

The most usual objective symptoms after meniscectomy in the present series were crepitation which occurred in more than 70 per cent of the patients. Tenderness on palpation of the medial side of medially as well as laterally meniscectomized knees was present in 16.4 per cent. Restricted active flexion occurred in 11.8 per cent, whereas 12.9 per cent of the patients had reduced muscular strength in the operated knee as compared with the nonoperated; decreased range of extension up to 10° in the operated knee compared with the nonoperated knee was present in 7.0 per cent of the cases.

Because of the relatively low frequency of clinical objective symptoms the material has been divided only into two groups when summing up these findings.

*Normal group:* To this group have been allocated not only patients without objective symptoms but also cases with a slight degree of a single objective finding, such as crepitations, reduced muscular strength, muscular atrophy or restriction of active flexion less than 10°.

*Group with objective findings:* All knees with more than one, or one pronounced objective finding, were assigned to this group.

The results, obtained on dividing the patients according to the above-mentioned principles, are shown in table 34. As seen in the table, a higher frequency of objective findings was present in laterally than medially meniscectomized knees, but the difference is not significant. A higher frequency of objective findings was observed for the women compared with the men, but this difference was also not significant.

No obvious correlation existed between objective findings and roent-

genologic signs of osteoarthritis or subjective complaints (tables 35 and 35 a).

The same analysis, as that done for the roentgenological findings and the subjective complaints, will be attempted in the following, in respect of the possible influence of different factors on the occurrence of objective clinical findings.

TABLE 34 Totally meniscectomized knees distributed according to the absence or presence of objective findings at the follow-up M = males, F = females  
% = M + F

## a. AGE AT TIME OF OPERATION

In the entire material of totally meniscectomized knees objective findings correlated with age at operation, with a borderline at 41 years of age (table 36) are more frequent in patients operated after than before 41 years of age, the difference being highly significant ( $X^2 = 16.80^{***}$  d. f. = 1). Similarly there was also a highly significant increase in objective findings in medially meniscectomized patients who were over 41 years when operated on compared with those under 41 at operation ( $X^2 = 18.20^{***}$  d. f. = 1). The difference observed in laterally meniscectomized knees was not significant. Men and women separately showed also higher frequency of objective findings when meniscectomy was performed on patients over 41 years. The differences are significant for both men ( $X^2 = 8.84^{**}$  d. f. = 1) and women ( $X^2 = 9.93^{**}$  d. f. = 1).

TABLE 36. Objective findings at follow-up correlated with age at operation in totally meniscectomized patients M = males, F = females. % = M + F

Operated meniscus	Age at operation	Total Number		Normal			With findings		
		M	F	M	F	%	M	F	%
Medial	Under 41 years	241	23	209	21	87.1	32	2	12.9
Lateral	" 41 "	49	7	35	7	75.0	14	0	25.0
Total	under 41 years	290	30	244	28	85.0	46	2	15.0
Medial	Over 41 years	86	21	61	12	68.2	25	9	31.8
Lateral	" 41 "	8	5	5	3	61.5	3	2	38.5
Total	over 41 years	94	26	66	15	67.5	28	11	32.5

## b. LATENCY PERIOD

When correlating the latency period with the objective findings no great differences are found for patients operated after a latency period under or over 6 months (table 37). Throughout, the differences are not statistically significant.

Correlation of the objective symptoms, on the one hand, with the length of the latency period, and, on the other, with the age at operation, gave no significant differences for latency periods under or over 6 months, either for patients under 41 or for those over 41 years at operation.

TABLE 37 Objective findings at follow-up correlated with the latency period in totally meniscectomized patients M = males, F = females % = M + F.

Operated meniscus	Latency period	Total Number		Normal Number		%	With findings Number		%
		M	F	M	F		M	F	
Medial	Under 6 months	177	28	150	21	83.4	27	7	16.6
Lateral	" 6 "	27	2	17	1	62.1	10	1	37.9
Total	Under 6 months	204	30	167	22	80.8	37	8	19.2
Medial	Over 6 months	150	16	120	12	79.5	30	4	20.5
Lateral	" 6 "	30	10	23	9	80.0	7	1	20.0
Total	over 6 months	180	26	143	21	79.6	37	5	20.4

### c. TYPE OF TRAUMA

When the objective findings are correlated with the factor preoperative trauma, no statistically significant differences are found in separate analyses for the entire material of total meniscectomies, for medial meniscectomies, for lateral meniscectomies, and for men and for women (table 38).

TABLE 38 Objective findings at follow-up correlated with the factor trauma in totally meniscectomized patients M = males, F = females % = M + F.

Operated Factor meniscus trauma	Total Number		Normal Number		%	With findings Number		%
	M	F	M	F		M	F	
Medial traumatic	279	36	230	28	81.9	49	8	18.1
Lateral " "	36	5	24	3	65.9	12	2	34.1
Total traumatic	315	41	254	31	80.1	61	10	19.9
Medial nontraumatic	48	8	40	5	80.4	8	3	19.6
Lateral " "	21	7	16	7	82.1	5	2	17.9
Total nontraumatic	69	15	56	12	81.0	13	7	19.0

#### d. LENGTH OF OBSERVATION PERIOD

Table 39 shows the distribution for the entire material when correlating the groups of objective findings with the groups of different observation periods. Existing differences are not statistically significant. This applies to the entire material, to medially operated, to laterally operated knees, and to men and women taken separately.

TABLE 39. *Objective findings at follow-up correlated with the length of observation period in totally meniscectomized patients. M = males, F = females.*  
 $\% = M + F.$

Period of observation	Total Number		Normal			With findings		
	M	F	M	F	%	M	F	%
4—13 years	219	44	176	35	80.2	43	9	19.8
14—23 "	106	8	87	6	81.6	19	2	18.4
24—33 "	53	4	42	2	77.2	11	2	22.8
34—43 "	6	0	5	0	83.3	1	0	16.7
Total	384	56	310	43	80.2	74	13	19.8

#### e. OTHER FACTORS POSSIBLY CONNECTED WITH THE DEVELOPMENT OF POSTOPERATIVE OBJECTIVE FINDINGS

*Preoperative clinical findings* did not show any significant influence on the occurrence of objective symptoms postoperatively.

*Secondary findings at operation* — with the exception of osteoarthritis — could not be analyzed statistically on account of the few cases recorded. Knees with signs of osteoarthritis diagnosed at operation showed, compared with knees without osteoarthritis at operation, an almost significantly higher frequency of objective findings at the follow-up investigation ( $X^2 = 5.38^*$  d. f. = 1).

*Postoperative complications* did not show any significant influence on the objective symptoms.

Nor was *postoperative muscular training* found to influence the objective symptoms significantly.

Knees treated with *postoperative fixation* showed a higher frequency

of objective findings compared with operated knees without postoperative fixation. The difference was almost significant ( $X^2 = 4.04^*$  d. f. = 1).

An almost significant increase in the frequency of objective findings was observed in patients with later start with *postoperative weight bearing* compared with patients who were allowed weight bearing earlier ( $X^2 = 8.56^+$  d. f. = 2).

Patients with longer *postoperative hospitalization* showed a significantly higher frequency of objective findings compared with those with shorter hospitalization ( $X^2 = 10.25^{**}$  d. f. = 1).

*Sport after operation* did not influence significantly the frequency of objective symptoms.

The *type of occupation* did not seem to have any significant importance for the occurrence of objective symptoms in the meniscectomized knee.

TABLE 40 Objective findings correlated with age at follow-up in totally meniscectomized patients M = males, F = females % =  $M + F$

Age at follow-up	Total Number		Normal			With findings		
			Number		%	Number		%
	M	F	M	F		M	F	
Under 41 years	118	19	98	18	84.9	20	1	15.1
41-60 "	212	25	178	19	83.1	34	6	16.9
Over 61 "	54	12	34	6	60.6	20	11	39.4
Total	384	56	310	43		74	13	

Age at the follow-up investigation correlated with the objective symptoms showed a higher frequency of objective findings in patients over 61 at the time of the follow-up, compared with younger patients (table 40). The observed difference is highly significant ( $X^2 = 19.20^{***}$  d. f. = 2). On further correlation with the length of the observation period a highly significant increase in the frequency of objective findings was found in the group with the shortest observation period among older than in younger patients at the time of the follow-up ( $X^2 = 22.10^{***}$  d. f. = 2). Thus, the high frequency of objective findings among older patients at the follow-up investigation seemed to be connected with the high frequency of objective findings among patients over 41 years at time of operation.

## f. SUMMARY OF OBJECTIVE SYMPTOMS

Very few authors have presented separately, objective findings present in meniscectomized knees during follow-up investigations.

In the present material the scanty occurrence of objective symptoms is striking. With regard to objective findings, there were no statistically significant differences between medially and laterally meniscectomized knees, nor between men and women.

The frequency of objective findings was higher for patients who were over 41 years at operation compared with those operated before they were 41. The difference is highly significant for the entire material of total meniscectomies ( $X^2 = **$ ), and for medially meniscectomized knees analysed separately ( $X^2 = **$ ), and significant for men ( $X^2 = *$ ) and for women ( $X^2 = *$ ) separately.

A latency period shorter or longer than 6 months did not influence the occurrence of objective findings significantly.

Nor did trauma, as aetiological factor for the injury of the semilunar cartilage, influence the occurrence of objective symptoms significantly.

The length of the observation period did not seem to play any significant role in the occurrence of objective symptoms.

With regard to the other factors which might possibly affect the occurrence of objective findings, the following proved to influence the results significantly.

Signs of degenerative arthritis at operation were followed by an almost significant increase in the frequency of objective findings at the follow-up examination ( $X^2 = *$ ). Postoperative fixation also showed an almost significant increase in the frequency of objective findings ( $X^2 = *$ ) and so did late weight bearing ( $X^2 = *$ ). A significant increase in objective findings was connected with a longer period of hospitalization ( $X^2 = *$ ). A more advanced age at the time of the follow-up, in combination with a short observation period and, consequently, advanced age at time of operation showed a highly significant increase in the objective findings ( $X^2 = **$ ).

#### 4. COMBINED TOTAL RESULTS

In several reports on follow-up investigations of meniscectomized series no account is given of the roentgenologic findings, subjective complaints or objective symptoms separately. Usually total results combining all three parameters are presented, and the patients are divided into 4 groups (table 41). The criteria for this classification, which can vary to some extent between the different authors, are discussed below in connection with the own classification. In some reports, in this respect the patients are divided for preference into 3 groups (table 42).

TABLE 41. Combined total results of earlier reported series distributed in 4 different groups

Authors	Total number	Excellent %	Good %	Fair %	Poor %	Type of oper.
Dengler (1938)	74	32.4	33.8	24.3	9.5	
Uebermuth (1941)	55	50.8	25.4	20.0	3.8	
Strels (1955)	82	74.4	24.4	1.2	0	partial
Scheibe (1963)	127	72.4	26.1	1.5	0	part + tot.
Leuschner & Weickert (1964)	91	57.1	31.9	11.0	0	"
Herschmann (1965)	163	69.7	20.0	9.1	1.2	total
Springorum (1966)	150	96.7	2.0	1.3	0	"
Tapper & Hoover (1969)	113	42.0	25.0	20.0	13.0	part + tot

TABLE 42. Combined total results of earlier reported series distributed in 3 different groups

Authors	Total number	Excellent %	Good %	Poor %
Raess (1930)	21	81.0	14.0	5.0
Spira (1933)	76	71.0	22.4	6.6
Meyer (1933)	98	72.4	27.6	
Andersson (1934)	23	60.9	30.4	8.7
Brechling (1942)	45	78.0	11.0	11.0
Nitter (1946)	35	82.5	11.7	5.8
Barfod & Biering (1956)	110	81.0	13.0	6.0

Reported results of follow-up investigations of meniscectomized patients are sometimes divergent.

Thus, it has been stated that a higher frequency of unsatisfactory total results occurs in laterally than in medially meniscectomized knees (Ale-

man & Friberg 1934, Uebermuth 1941), but also that the frequency of satisfactory combined results is higher after lateral than after medial meniscectomies (Meier 1933).

Several authors have reported a distinctly higher frequency of unsatisfactory total results in women compared with men (Aleman & Friberg 1934, Brechling 1942, Lagergren 1953, Barfod & Biering 1956, Tapper & Hoover 1969).

It has further been reported that "excellent" total results were observed in all 25 followed-up patients, who were over 60 years at the time of the operation (Litchman et al. 1966).

### *Own investigations*

The main part of the present material, which comprises all totally meniscectomized knees, has been subjected to separate analyses of the roentgenologic findings, the subjective complaints, and the objective symptoms, and has also been analyzed in respect of different factors which might possibly cause deterioration of the results. The entire material investigated will also be analyzed in the same way, with regard to the combined total results.

In conformity with several other authors the material has been divided into 4 groups. Certain variations in the criteria used for the division of the material in relation to those of other authors could not be avoided. The difficulties in obtaining entirely comparable principles of classification are illustrated, for example, by the fact that Streli (1955) includes, in his total group of "Gut" knees, with a range of motion "from fully extended up to 70° flexed position", while Springorum (1966) considers that knees, with such a restriction of motion "up to 70°", can obviously not be regarded as "Gut".

An account of the criteria used for allocation of the patients to the different groups is given below:

*Group Excellent:* comprises 1. patients with no subjective complaints, objective symptoms and roentgenologic findings. 2. cases with roentgenologic signs of osteoarthritis of grade I, if no subjective complaints or objective symptoms were simultaneously present, and 3. cases with subjective complaints of the type *Good* (1+), if there were no roentgenologic findings.

To *group Good:* were allocated patients with 1. grade II roentgenologic findings at most, if at the same time the subjective complaints were not more than of the type *Good* (1+), and there were no objective symp-

toms. 2. Subjective complaints of type *Fair* (3+) or less, but with simultaneous grade I roentgenologic findings at most and no objective findings.

*Group Fair:* 1. Most of the patients in this group had grade II roentgenologic findings and subjective complaints varying between *Good* and *Fair*, with objective findings. 2. Here were also included cases with grade III roentgenologic osteoarthritis, but then in association with either mild or no subjective complaints of group *Good* or *Excellent* and with objective findings. 3. Patients with grade II or I roentgenologic findings, but with simultaneous subjective complaints of type *Bad*, and with objective findings, were also placed in this group.

*Group Poor:* All the patients in this group had grade III roentgenologic findings, subjective complaints varying between *Fair* and *Bad*, as well as objective findings.

Table 43 shows the distribution of the totally meniscectomized knees in accordance with the grouping described above.

TABLE 43 Combined total results at follow-up in totally meniscectomized patients distributed in 4 groups M = males, F = females % = M + F

Operated meniscus	Total		Excellent			Good			Fair			Poor		
	Number		Number		%	Number		%	Number		%	Number		%
	M	F	M	F		M	F		M	F		M	F	
Medial	327	44	259	22	75.7	47	14	16.5	16	6	5.9	5	2	1.9
Lateral	57	12	41	8	71.0	14	3	24.7	2	1	4.3	0	0	0
Total	384	56	300	30	75.0	61	17	17.7	18	7	5.7	5	2	1.6

When comparing medially and laterally meniscectomized knees no significant differences were observed in respect of the combined late results.

A significantly higher frequency of unsatisfactory combined total results of group *Fair* and *Poor* was observed in the women as compared with the men ( $X^2 = 16.53^{***}$  d.f. = 2).

### Comments

If a comparison is made between the results of this material and those reported by other authors, it will be found that more satisfactory combined late results were obtained in the present investigation than in several earlier series (Dengler 1938, Uebermuth 1941, Leuschner & Weickerd 1964, Herschmann 1965). However, better results have also

been reported by earlier authors (Streli 1955, Scheibe 1963, Strelec & Wozleka 1964, Springorum 1966). Comparison of reported observations from series where the material is allocated to 3 and 4 groups respectively gives no reliable results. If, however, the group *Poor* in the former classification is considered to correspond to groups *Fair* and *Poor* in the classification with 4 groups, the frequency of unsatisfactory combined total results will be approximately the same according to both systems of classification.

In the present material there was a significantly higher frequency of unsatisfactory total results in women compared with men, which verifies the results reported by some earlier authors (Aleman & Friberg 1934, Brechling 1942, Lagergren 1953, Barfod & Bierring 1956, Tapper & Hoover 1969).

With regard to the combined total results no significant differences existed between medially meniscectomized and laterally operated knees, a fact which does not agree with some earlier reports (Meier 1934, Aleman & Friberg 1934, Uebermuth 1941).

In what follows analyses of the combined total results will be made with regard to the same factors, as for the roentgenologic findings, the subjective complaint, and the objective symptoms.

#### a. AGE AT TIME OF OPERATION

It has been stated earlier that the more advanced the age of the patient at operation the higher will be the frequency of unsatisfactory results, and the conclusion has been drawn that in patients over 40—45, meniscectomy should be performed only if absolutely necessary (Raess 1930, Meier 1933, Dengler 1938, Scheibe 1963, Herschmann 1965). It has also been maintained, however, that the age of the patient at operation does not affect the subsequent total result (Andersson 1934, Barfod & Bierring 1956, Saugmann-Jensen 1963, Litchman et al. 1966). A lower mean age at operation for patients with unsatisfactory results in the operated knee has even been reported by Nitter (1946).

#### *Own investigations*

When correlating the combined total results with age at operation, for the entire material of total meniscectomies a higher frequency of unsatisfactory results of groups *Fair* and *Poor* was found for patients operated

TABLE 44 Combined total results correlated with age at operation. M = males, F = females. % = M + F.

Operated		Age at meniscus operation		Total Number		Excellent Number		%	Good Number		%	Fair Number		%	Poor Number		%
		M	F	M	F	M	F		M	F		M	F				
Medial	Under 41 years	241	23	191	14	77.7	39	7	17.4	10	2	4.5	1	0	0.4		
Lateral	Under 41 years	49	7	35	4	69.6	12	3	26.8	2	0	3.6	0	0	0		
Total Under 41 years		290	30	226	18	76.2	51	10	19.1	12	2	4.4	1	0	0.3		
Medial	Over 41 years	86	21	68	8	71.0	8	7	14.0	6	4	9.4	4	2	5.6		
Lateral	Over 41 years	8	5	6	4	76.9	2	0	15.4	0	1	7.7	0	0	0		
Total Over 41 years		94	26	74	12	71.7	10	7	14.2	6	5	9.1	4	2	5.0		

when over 41 years compared with those operated before 41 (table 44). The difference is significant ( $X^2 = 12.21^{**}$  d. f. = 2). A similar, significant difference was also obtained for medially meniscectomized ( $X^2 = 10.78^{**}$  d. f. = 2), but not for laterally meniscectomized knees alone. A comparison for men and women separately showed an almost significantly higher frequency of unsatisfactory results for men operated after 41 years than for those operated before 41 ( $X^2 = 6.65^*$  d. f. = 2). A similar difference for women was not significant.

#### Comments

In the present material a higher frequency of unsatisfactory combined results was found for patients operated when over 41 years compared with those operated under 41. This appears to verify observations reported by earlier investigators (Raess 1930, Meier 1933, Dengler 1938, Scheibe 1963, Herschmann 1965).

#### b LATENCY PERIOD

Higher frequency of unsatisfactory results of groups *Fair* and *Poor* has been reported following meniscectomy with long latency period, i. e. if a long time elapsed between trauma, or the onset of the complaint, and the operation (Meier 1933, Dengler 1938, Nitter 1946, Strehl 1955, Barfod &

been reported by earlier authors (Streli 1955, Scheibe 1963, Strelec & Wozleka 1964, Springorum 1966). Comparison of reported observations from series where the material is allocated to 3 and 4 groups respectively gives no reliable results. If, however, the group *Poor* in the former classification is considered to correspond to groups *Fair* and *Poor* in the classification with 4 groups, the frequency of unsatisfactory combined total results will be approximately the same according to both systems of classification.

In the present material there was a significantly higher frequency of unsatisfactory total results in women compared with men, which verifies the results reported by some earlier authors (Aleman & Friberg 1934, Brechling 1942, Lagergren 1953, Barfod & Bierring 1956, Tapper & Hoover 1969).

With regard to the combined total results no significant differences existed between medially meniscectomized and laterally operated knees, a fact which does not agree with some earlier reports (Meier 1934, Aleman & Friberg 1934, Uebermuth 1941).

In what follows analyses of the combined total results will be made with regard to the same factors, as for the roentgenologic findings, the subjective complaint, and the objective symptoms.

#### a. AGE AT TIME OF OPERATION

It has been stated earlier that the more advanced the age of the patient at operation the higher will be the frequency of unsatisfactory results, and the conclusion has been drawn that in patients over 40—45, meniscectomy should be performed only if absolutely necessary (Raess 1930, Meier 1933, Dengler 1938, Scheibe 1963, Herschmann 1965). It has also been maintained, however, that the age of the patient at operation does not affect the subsequent total result (Andersson 1934, Barfod & Bierring 1956, Saugmann-Jensen 1963, Litchman et al. 1966). A lower mean age at operation for patients with unsatisfactory results in the operated knee has even been reported by Nitter (1946).

#### *Own investigations*

When correlating the combined total results with age at operation, for the entire material of total meniscectomies a higher frequency of unsatisfactory results of groups *Fair* and *Poor* was found for patients operated

Efskind 1939, Tapper & Hoover 1969). If the combined results are correlated with the latency periods, over and under 6 months respectively and at the same time with the age at operation, the length of the latency period will not be found to influence significantly the results for patients operated either before or after 41 years of age.

### c. TYPE OF TRAUMA

Andersson (1934) and Strelé (1955) consider that trauma as etiologic factor for the injury of the semilunar cartilage may be the cause of less satisfactory total results. Andersson (1934) found a fourfold unsatisfactory combined result for meniscectomies following a traumatic injury of the semilunar cartilage compared with nontraumatic cases. Tapper & Hoover (1969) consider that the less satisfactory results observed in young patients, operated before the age of 20 were due to severe trauma being responsible for the injury of the semilunar cartilage. A contrary opinion was held by Springorum (1966), who considers that less satisfactory results follow meniscectomies performed for nontraumatic ruptures. In such cases the rupture of the semilunar cartilage would be due to a higher degree of degeneration in both the semilunar cartilage and the knee in a whole, and hence the unsatisfactory results.

#### *Own investigations*

When correlating the combined groups of results after meniscectomy in traumatic and nontraumatic cases (table 46), no significant difference is found in the frequency of unsatisfactory results of groups *Fair* and *Poor*.

TABLE 46 Combined total results correlated with the factor trauma M = males, F = females \*% = M + F

Operated meniscus	Factor trauma	Total		Excellent		Good		Fair		Poor	
		Number		Number		Number		Number		Number	
		M	F	M	%	M	%	M	%	M	%
Medial	traumatic	279	36	225	77.5	36	12.5	14	5.0	4	1.5
Lateral	"	36	5	24	65.8	11	29.3	1	2.8	0	0.0
Total	traumatic	315	41	249	76.1	47	13.8	15	4.5	4	1.2
Medial	nontraumatic	48	8	34	66.0	11	23.2	2	5.4	1	2.5
Lateral	"	21	7	17	78.6	3	17.8	1	3.6	0	0.0
Total	nontraumatic	69	15	51	70.2	14	21.4	3	4.8	1	1.6

Bierring 1956, Scheibe 1963, Leuschner & Weickert 1964, Herschmann 1965). On this account these authors recommend that operation for ruptured semilunar cartilage should be performed as early as possible, but only after the acute symptoms have subsided. There are also some authors who were unable to find any clear-cut connection between the length of the latency period and a higher frequency of unsatisfactory results after a meniscectomy (Raess 1930, Spira 1933, Andersson 1934, Efskind 1939, Tapper & Hoover 1969). There is no unanimity about the demarcation line between a short and a long latency period, but many authors take 6 months as the borderline.

### *Own investigations*

Table 45 shows the groups of combined results correlated with latency periods under and over 6 months. The small differences in the distribution of unsatisfactory results between short and long latency periods are not significant.

TABLE 45. Combined total results correlated with the latency period. M = males, F = females. % = M + F.

Operated meniscus	Latency period	Total Number		Excellent Number		%	Good Number		%	Fair Number		%	Poor Number		%
		M	F	M	F		M	F		M	F		M	F	
Medial	Under 6 months	177	28	142	13	75.6	24	9	16.1	10	5	7.3	1	1	1.0
Lateral	Under 6 months	27	2	18	1	65.5	8	0	27.6	1	1	6.9	0	0	0
Total	Under 6 months	204	30	160	14	74.4	32	9	17.5	11	6	7.3	1	1	0.8
Medial	Over 6 months	150	16	117	9	75.9	23	5	16.9	6	1	4.2	4	1	3.0
Lateral	Over 6 months	30	10	23	7	75.0	6	3	22.5	1	0	2.5	0	0	0
Total	Over 6 months	180	26	140	16	75.8	29	8	17.9	7	1	3.9	4	1	2.4

### *Comments*

In the present material it was not possible to demonstrate a deterioration in the combined results due to a longer latency period. This agrees with the conception that the length of the latency period does not affect the postoperative combined results (Raess 1930, Spira 1933, Andersson 1934,

## Comments

The results of this material show that the length of the observation period does not play any part in the development of the combined results, which is in agreement with the earlier reports mentioned above.

## e. OTHER FACTORS POSSIBLY CAUSING DETERIORATION OF RESULTS

### *Preoperative clinical findings*

MacAusland (1931) considers that preoperative clinical findings, such as lockings, effusion or combinations of these can often cause unsatisfactory combined results. Barfod & Bierring (1956), on the other hand, concluded that the frequency of lockings and effusion have no detrimental influence on the combined results.

### *Own investigations*

As is evident from table 48, preoperative clinical findings were about equally distributed among the groups of combined total results. Existing small differences, with regard of unsatisfactory results, between knees with or without preoperative clinical findings were not significant.

TABLE 48 Combined total results correlated with preoperative findings M = males, F = females % = M + F

Preoperative findings	Total Number		Excellent		Good		Fair		Poor	
	M	F	M	F	M	F	M	F	M	F
Only lockings	99	10	80	6	14	3	3	0	2	1
effusion	26	24	65	14	14	7	7	3	0	0
" haemarthrosis	4	0	4	0	0	0	0	0	0	0
Lockings + effusion	113	8	86	3	20	2	4	3	3	0
" + haemarthrosis	8	0	7	0	1	0	0	0	0	0
Total with preop find	310	42	242	23	49	12	14	6	5	1
%	100.0		75.3		17.3		5.7		1.7	
Without preop findings	74	14	58	7	12	5	4	1	0	1
%	100.0		73.9		19.3		5.7		1.1	

## Comments

Contrary to Andersson (1934), Strelt (1955) and Tapper & Hoover (1969), in the present material there is no significant difference in the combined results after meniscectomy between traumatic and non-traumatic cases. Nor do the present results verify the view, that less satisfactory results would be achieved after meniscectomy in nontraumatic cases (Springorum 1966).

## d. OBSERVATION PERIOD

Many authors consider that a sufficiently long observation period is required in order to be able to assess the late results following a meniscectomy. The length of a sufficiently long observation period is estimated, however, differently by different authors and, varies between 10 and 20 years; in general about 14—15 years.

It has been stated in this context that the length of the observation period does not play any role in the quality of the late results (Brechtling 1942, Barfod & Bierring 1956, Herschmann 1965). Better results have been reported, however, after a long observation period (Meier 1933, Spira 1933, Springorum 1966), but there are also reports to the contrary (Nitter 1946).

### Own investigations

As is evident from table 47 only small differences existed between the various groups of observation periods in respect of unsatisfactory combined results of groups *Fair* and *Poor*. These differences were not significant.

TABLE 47. Combined total results correlated with the observation period M = males, F = females % = M + F

Period of observation	Total		Excellent			Good			Fair			Poor		
	Number		Number		%	Number		%	Number		%	Number		%
	M	F	M	F		M	F		M	F		M	F	
4—13 years	219	44	179	26	78.0	27	13	15.2	9	4	4.9	4	1	1.9
14—23 "	106	8	79	4	72.8	21	2	20.2	6	1	6.1	0	1	0.9
24—33 "	53	4	36	11	63.2	13	2	26.3	3	2	8.8	1	11	1.7
34—43 "	6	0	6	0	100.0	0	0	0	0	0	0	0	0	0
Total	384	56	300	30		61	17		18	7		5	2	

## Postoperative complications

Efskind (1939) stated that in his series less satisfactory results were observed consistently in patients with prolonged effusion in the joint after a meniscectomy.

### Own investigations

The frequency of different postoperative complications with regard to the combined results is demonstrated in table 50. No patient belonging to group *Poor* had had such complications. No statistically significant differences in the frequency of unsatisfactory results of group *Fair* and *Poor* were found between patients with or without different postoperative complications.

TABLE 50 Combined total results correlated with postoperative complications  
M = males, F = females

Postoperative complications	Total Number		Excellent		Good		Fair		Poor	
	M	F	M	F	M	F	M	F	M	F
Persisting effusion	14	1	7	1	6	0	1	0	0	0
Hæmarthrosis	19	1	13	1	5	0	1	0	0	0
Signs of infection	19	2	17	1	2	0	0	1	0	0

### Comments

The results obtained from the present material show that postoperative complications do not cause deterioration of the combined late results. This observation is contrary to the findings of Efskind (1939).

### Postoperative treatment

Fixation with some type of splint or plaster is applied as a postoperative routine by many authors. Several others prescribe muscular training as part of their routine. No information is given, however, about the effect of these therapeutic managements on the combined results after meniscectomy. There is lack of information also regarding the influence of various routine measures on the late results: when postoperatively the patient is allowed to begin weight bearing on his leg, and the length of postoperative hospitalization.

### Comments

In contrast to the data reported by MacAusland (1931), the present observations show that existence of preoperative clinical findings did not influence significantly the combined late results. This is in agreement with the results reported by Barfod & Bierring (1956).

### Secondary findings at operation

Existence of varying intra-articular changes, among others, degenerative arthritis and lesions of the ligaments, diagnosed at the time of meniscectomy, have been reported to deteriorate the prognosis concerning the combined late results (Streli 1955, Springorum 1966, Mohing 1966).

### Own investigations

Table 49 shows the frequency of different secondary findings at operation. On account of the few cases with secondary findings at operation, other than osteoarthritis, it was not possible to analyze these statistically. The frequency of unsatisfactory total results of groups *Fair* and *Poor* was, however, found to be higher in patients with than without osteoarthritis diagnosed at operation. The observed difference was highly significant ( $X^2 = 26.44^{**}$  d. f. = 3).

TABLE 49. Combined total results correlated with the various operative findings  
M = males, F = females

Operative findings	Total Number		Excellent		Good		Fair		Poor	
	M	F	M	F	M	F	M	F	M	F
Injuries of coll lig	3	1	1	1	2	0	0	0	0	0
"    "    cruc. "	5	0	5	0	0	0	0	0	0	0
Chondr patellae	9	2	4	1	2	1	2	0	1	0
Osteochondr. dissec	8	1	5	0	1	1	1	0	1	0
Osteoarthritis	32	10	19	5	5	3	5	1	3	1

### Comments

The existence of osteoarthritis at operation has been shown to deteriorate significantly the combined late results after meniscectomy. The role possibly played by other secondary findings at operation could not be analyzed statistically on account of the few cases with such findings according to the available information in the hospital records.

### Postoperative complications

Etskind (1939) stated that in his series less satisfactory results were observed consistently in patients with prolonged effusion in the joint after a meniscectomy.

### Own investigations

The frequency of different postoperative complications with regard to the combined results is demonstrated in table 50. No patient belonging to group Poor had had such complications. No statistically significant differences in the frequency of unsatisfactory results of group Fair and Poor were found between patients with or without different postoperative complications.

TABLE 50 Combined total results correlated with postoperative complications  
M = males, F = females

Postoperative complications	Total Number		Excellent		Good		Fair		Poor	
	M	F	M	F	M	F	M	F	M	F
Persisting effusion	14	1	7	1	6	0	1	0	0	0
Haemarthrosis	19	1	13	1	5	0	1	0	0	0
Signs of infection	19	2	17	1	2	0	0	1	0	0

### Comments

The results obtained from the present material show that postoperative complications do not cause deterioration of the combined late results. This observation is contrary to the findings of Etskind (1939).

### Postoperative treatment

Fixation with some type of splint or plaster is applied as a postoperative routine by many authors. Several others prescribe muscular training as part of their routine. No information is given, however, about the effect of these therapeutic managements on the combined results after meniscectomy. There is lack of information also regarding the influence of various routine measures on the late results: when postoperatively the patient is allowed to begin weight bearing on his leg, and the length of postoperative hospitalization

## Own investigations

During the long period covered by this material a number of routines must have been prevalent with regard to the above-mentioned postoperative forms of treatment. Thus, information on postoperative muscular training has been obtained for 199 patients, and application of postoperative fixation for 171 patients. This enables statistical analysis of the observed differences, and, hence reliable information can be obtained regarding the influence of these therapeutic measures on the combined results.

TABLE 51. Combined total results correlated with different forms of postoperative treatment. M = males, F = females. % = M + F.

Postoperative treatment	Total Number		Excellent		Good		Fair		Poor	
	M	F	M	F	M	F	M	F	M	F
Muscular training	170	29	143	17	19	9	6	2	2	1
%	100		80.4		14.1		4.0		1.5	
Without training	214	27	157	13	42	8	12	5	3	1
%	100		70.5		20.7		7.1		1.7	
Fixation by splint or plaster	150	21	120	11	22	7	4	2	4	1
%	100		76.6		17.0		3.5		2.9	
Without fixation	234	35	180	19	39	10	14	5	1	1
%	100		74.0		18.2		7.1		0.7	

Table 51 shows the allocation of the material to the different groups of combined total results, for the cases where muscular training was applied, and for patients treated with postoperative fixation separately. There were no significant differences in the frequency of unsatisfactory combined results between patients who were prescribed postoperative muscular training and those who were not, or between patients treated with or without postoperative fixation.

When correlating the combined late results with the time when weight bearing was first allowed postoperatively (table 52), it was found that the frequency of unsatisfactory results was higher for patients who began weight bearing later compared with those who began earlier, i. e. within 2 weeks after the operation. The differences were statistically significant ( $X^2 = 13.66^{**}$  d. f. = 4).

The length of hospitalization did not influence significantly the frequ-

ency of unsatisfactory late results in patients discharged within the first two weeks after meniscectomy or later (table 53).

### Comments

The fact that postoperative muscular training does not influence the frequency of unsatisfactory late results may not be surprising. Postoperative fixation was, however, expected to cause bad results, as was the case with roentgenologic findings<sup>8)</sup> and objective symptoms. It is evident, however, that the fact that subjective complaints, were not influenced by postoperative fixation, probably affected the combined results to a greater extent than did the roentgenologic findings and the objective symptoms together. The observation that a delayed start with weight bearing caused significantly less satisfactory results is difficult to explain. It is possible, however, that patients with preoperative signs of roentgenologic osteoarthritis, osteoarthritis diagnosed at operation, or advanced age at operation, were not allowed early weight bearing and then the bad late results must be assigned to these factors rather than to the time of weight bearing per se.

<sup>8)</sup> see footnote page 41

### *Age at the follow-up investigation*

The mean age at the follow-up investigation was for patients with total meniscectomy  $47.5 \pm 0.6$  years. When age at the follow-up investigation is correlated with the different groups of combined late results (table 54) there is a distinctly higher frequency of unsatisfactory results of group *Fair* and *Poor* for patients over 61 compared with younger persons at the time of the follow-up. The differences were highly significant ( $X^2 = 19.60^{***}$  d. f. = 4). A further correlation with different observation periods did not show any statistically significant effect on the results for the different age groups at the time of the follow-up.

TABLE 54. Combined total results distributed by patients' age at the follow-up examination. M = males, F = females. % = M + F.

Age at follow-up	Total		Excellent			Good			Fair			Poor		
	Number		Number		%	Number		%	Number		%	Number		%
	M	F	M	F		M	F		M	F		M	F	
Under 41 years	118	19	98	12	80.3	16	6	16.1	4	1	3.6	0	0	0
41-60 "	212	25	162	13	73.8	39	9	20.3	9	2	4.6	2	1	1.3
Over 61 "	54	12	40	5	68.2	6	2	12.1	5	4	13.6	3	1	6.1
Total	384	56	300	30		61	17		18	7		5	2	

### *Comments*

The observation of a higher frequency of unsatisfactory combined late results in patients over 61 at the time of the follow-up compared with younger patients can hardly be explained by any cause other than generalized changes of the knee with advancing age; meniscectomy might possibly promote the rapid development of such changes.

### *Sport and occupation after operation*

Raess (1930) reported that the degree of occupational strain for the operated knee after the operation does not influence the late results and Meier (1933) stated that all the patients in his own material were able to return after the operation to their previous, often heavy, work.

### *Own investigations*

Practising of sport after the operation did not cause deterioration in the combined late results (table 55). That so few of those who practised

TABLE 55 *Combined total results distributed according to the factor postoperative sport M = males, F = females*

Postoperative sport	Total		Excellent		Good		Fair		Poor	
	M	F	M	F	M	F	M	F	M	F

Total	139	2	122	1	15	1	2	0	0	0

athletic activities after operation were placed in the groups *Fair* or *Poor*, can hardly be due to the fact, however, that sport after operation improved the results; it is more probable that patients with knee complaints after meniscectomy abstained from sport.

When the degree of occupational strain is correlated with the different groups of combined total results (table 56), it is found that the lowest frequency of unsatisfactory results occurred among those patients who, after operation, had the most knee-straining work. No statistically significant differences in the frequency of unsatisfactory late results were found for patients with heavier work compared with those having less knee-straining work after operation.

TABLE 56 *Combined total results distributed by type of occupational knee strain after operation M = males, F = females % = M + F*

Total	384	56	300	30		51	17		18	7		5	2	

### Comments

The results of the present investigation show that sport after meniscectomy does not aggravate the late results for the operated knee. This investigation also verifies earlier reports, namely, that the type of postoperative occupation does not influence the combined total results (Raess 1930, Meier 1933).

## f. SUMMARY OF THE COMBINED TOTAL RESULTS

The results reported in this part can be summarized as follows:

a. In the present material of totally meniscectomized knees no significant differences, between medially and laterally operated knees, could be demonstrated with regard to the combined total results. The frequency of unsatisfactory total results was, however, higher for women compared with men, and this difference is highly significant ( $X^2 = ***$ ).

b. Patients over 41 years at time of operation showed a higher frequency of unsatisfactory combined results of group *Fair* and *Poor* compared with patients under 41 at operation. Differences obtained in this respect are significant for the entire material of total meniscectomies ( $X^2 = **$ ) and for medially operated knees alone ( $X^2 = **$ ), and almost significant for men alone ( $X^2 = \cdot$ ). For laterally operated knees and for women separately the differences were not significant.

c. The length of the latency period was not of significant importance for the occurrence of unsatisfactory combined late results after meniscectomy.

d. No significant differences, could be shown in the combined results after meniscectomy, between patients whose lesion of the semilunar cartilage was of traumatic origin and those where it was not.

e. No significant differences, in the frequency of unsatisfactory total results of group *Fair* and *Poor* could be shown to exist in this material, between patients with shorter and longer observation periods respectively.

f. The occurrence of preoperative clinical findings has not been found to cause deterioration of the combined late results to a significant extent.

g. Osteoarthritis established at operation has caused a highly significant deterioration of the combined late results after meniscectomy ( $X^2 = ***$ ).

h. Postoperative complications, such as effusion, haemarthrosis or signs of infection have not been shown to be of significant importance for the combined late results.

i. Muscular training or fixation after the operation had no significant influence on the late results.

j. The length of hospitalization did not influence the frequency of unsatisfactory results in a significant way. However, significantly higher frequency of unsatisfactory combined total results occurred in cases where weight bearing was allowed first after the 2nd postoperative week than in those where it was introduced earlier ( $X^2 = **$ ).

k. The frequency of unsatisfactory results was significantly higher for

patients over 61 at the follow-up investigation compared with those under 61 ( $X^2 = **$ ).

1. Athletic activities after operation do not seem to have caused deterioration of the late results after meniscectomy. Nor has occupational knee-strain postoperatively influenced the combined late results in any significant way.

## 5. TOTAL MENISCECTOMIES EXCLUDING CASES WITH PRE-OPERATIVE ROENTGENOLOGIC OSTEOARTHRITIS OR OSTEOARTHRITIS DIAGNOSED AT OPERATION

In earlier investigations of meniscectomized patients no special attention has been paid to cases with preoperative roentgenologic signs of osteoarthritis. Materials including such cases are inhomogeneous and the latter might, therefore, influence the degree of significance of the obtained results. Preoperative roentgenograms available for comparison at the time of follow-up examination restrict to some extent such an undesired interference.

The material reported on hitherto has included all cases of total meniscectomy. As mentioned earlier, preoperative radiographies were not available during the follow-up investigation. In order to ascertain whether the obtained results were influenced in any degree by the presence in the material of such patients as had preoperative roentgenologic signs of osteoarthritis or osteoarthritis diagnosed at operation, these cases were excluded and then the remaining material was analyzed in respect of roentgenologic findings and combined late results. A short account of the most important results obtained from these analyses will be given herewith.

TABLE 57 Distribution of totally meniscectomized knees in the different groups of roentgenologic osteoarthritis by age at operation. Patients with preoperative roentgenologic osteoarthritis or osteoarthritis diagnosed at operation are excluded. M = males, F = females. % =  $M + F$

Age at operation	Total		Group 0			Group I			Group II			Group III		
	Number		Number		%	Number		%	Number		%	Number		%
	M	F	M	F		M	F		M	F		M	F	
Under 41 years	270	26	159	14	58.5	87	9	32.4	22	3	8.5	2	0	0.6
Over 41 "	66	16	33	8	50.0	32	6	46.3	1	2	3.7	0	0	0
Total	336	42	192	22	56.6	119	15	35.5	23	5	7.4	2	0	0.5

When, after this exclusion, roentgenologic osteoarthritis at follow-up is correlated with age at time of operation, *there is no significant difference in the frequency of degenerative arthritis of grade II and III between patients operated before or after 41 years of age (table 57).* The same conditions were found to exist on correlating the combined late results with age at operation.

The length of the latency periods shows no significant influence on either the frequency of roentgenologic osteoarthritis or the frequency of unsatisfactory combined results.

The length of the observation period showed, even under these conditions, a highly significant increase in the frequency of roentgenologic osteoarthritis in the groups with longer observation period ( $X^2 = 30.65^{***}$  d. f. = 4). On the other hand, an almost significant higher frequency of unsatisfactory combined late results of groups *Fair* and *Poor* was obtained in the new analysis with increasing length of the observation period ( $X^2 = 11.03^*$  d. f. = 4), which was not the case when the total number of meniscectomies was analyzed.

TABLE 58. *Distribution of totally meniscectomized knees in the different groups of roentgenologic osteoarthritis according to postoperative muscular training. Patients with preoperative roentgenologic osteoarthritis or osteoarthritis diagnosed at operation are excluded.*

	Total Number	Group 0 Number %	Group I Number %	Group II Number %	Group III Number %

TABLE 59 *Distribution of totally meniscectomized knees in the different groups of roentgenologic osteoarthritis at follow-up according to postoperative fixation. Patients with preoperative roentgenologic osteoarthritis or osteoarthritis diagnosed at operation are excluded.*

	Total Number	Group 0 Number %	Group I Number %	Group II Number %	Group III Number %
Fixation postoperatively	147	77 52.4	65 44.2	4 2.7	1 0.7
No fixation "	231	137 59.3	69 29.9	24 10.4	1 0.4
Total	378	214	134	28	2

roentgenologic osteoarthritis ( $X^2 = 11.93^{***}$  d. f. = 2) as well as unsatisfactory combined results ( $X^2 = 163.90^{***}$  d. f. = 2) (table 58 and 58 a).

From table 59 it is evident that patients treated with fixation with splints after operation showed a lower frequency of roentgenologic osteoarthritis of grade II and III when compared with patients treated without fixation. The difference is highly significant ( $X^2 = 12.21^{***}$  d. f. = 2). On the other hand, even now there was no difference in respect of unsatisfactory combined results between patients with or without postoperative fixation.

The time when weight bearing was first allowed and the length of hospitalization did not show any significant differences with regard to roentgenologic osteoarthritis or unsatisfactory combined results. Apparently the previously observed significant differences in this respect were due to the fact that patients, with preoperative roentgenologic signs of degenerative arthritis or osteoarthritis at time of operation, were allowed to start weight bearing later and were also discharged from hospital later.

## Results of follow-up investigation after partial meniscectomy

Reports regarding results of follow-up investigations of partially meniscectomized patients are scarce (table 41). Strelt (1955), and Böhler (1955) have reported the results for a material consisting solely of partial meniscectomies. Scheibe (1963) and Leuschner & Weickert (1964) present results for totally and for partially meniscectomized knees separately. Tapper & Hoover (1969) state that the results after partial meniscectomy are not more satisfactory than after total meniscectomy, except when partial meniscectomy is performed in cases of so-called "bucket-handle" ruptures of the semilunar cartilage, where the results are better. Strelt (1955) reported separately the results for roentgenologic findings and for combined total results, but not for subjective complaints or objective symptoms.

The material under review comprised only 21 partially resected cases, 17 of which were medially and 4 laterally meniscectomized. Only 2 women were partially meniscectomized, both medially. This material is too small to afford any possibility of an analysis similar to that of the material of total meniscectomies. A short account of this material will, however, be given.

### 1. ROENTGENOLOGIC RESULTS

In accordance with the principles of classification applied for the totally meniscectomized knees, the partial meniscectomies can be grouped as shown in table 60 (p. 86). The frequency of roentgenologic signs of degenerative arthritis was 9.5 per cent. Compared with the results obtained by Strelt (1955) (table 41) who reported cases with osteoarthritis in 14.6 per cent, the results of the present material seem to be somewhat more

satisfactory. With regard to the frequency of roentgenologic findings of osteoarthritis, there were no significant differences between totally and partially meniscectomized knees.

Only one patient was operated when over 41. Twenty patients were younger than 41 at time of operation. The two patients in group II were operated with a latency period less than 6 months, and in both the rupture of the semilunar cartilage was of traumatic origin. — Regarding the observation period these two patients belonged to group 14—23 years. Moreover, it may be mentioned that none of the partially meniscectomized patients had postoperative complications.

## 2. SUBJECTIVE COMPLAINTS

When classifying the material into different groups with regard to the subjective complaints, the same criteria were used as for total meniscectomies. Fifteen men and 1 woman among the partially meniscectomized patients were allocated to the group *Excellent*, 3 men and 1 woman to the group *Good*, and only 1 man to the group *Fair*. None of these patients had subjective complaints of the type *Bad*. When the frequency of subjective complaints of groups *Fair* and *Bad* was compared between partially and totally meniscectomized patients no significant differences were found.

## 3. OBJECTIVE SYMPTOMS

With regard to objective symptoms the partially meniscectomized patients were assessed in the same way as the totally meniscectomized. Seventeen men and 1 woman belonged to the *normal* group, and 2 men and 1 woman to the group *with symptoms*. There was no significant difference between totally meniscectomized and partially meniscectomized knees in the frequency of cases with symptoms.

## 4. COMBINED RESULTS FOR PARTIAL MENISCECTOMIES

The principles used for the assessment of the combined results for the totally meniscectomized knees were also used for the partially operated. Fifteen men and 2 women belonged to the group *Excellent*, 3 men to the group *Good*, and 1 man to the group *Fair*. Observed differences in frequency of unsatisfactory combined results between totally and partially meniscectomized patients were not significant.

TABLE 60. *Partially meniscectomized patients distributed by different groups of roentgenologic osteoarthritis at follow-up. M = males, F = females.*  
 $\% = M + F$ .

Operated meniscus	Total Number		Group 0			Group I			Group II			Group III		
	M	F	M	F	%	M	F	%	M	F	%	M	F	%
Medial	15	2	9	2	64.7	5	0	29.4	1	0	5.9	0	0	0
Lateral	4	0	3	0	75.0	0	0	0	1	0	25.0	0	0	0
Total	19	2	12	2	66.7	5	0	23.8	2	0	9.5	0	0	0

TABLE 61. *"Double-operated" knees distributed according to the combined total results.*

"Double-operated" knees	Excellent	Good	Fair	Poor
Both knees medial	18	2	0	0
One medial + other lateral	3	3	0	0
Same knee medial and lateral	4	1	1	0
Number of operated knees	25	6	1	0

## CHAPTER VI

### "Double-operated"

There are few reports regarding cases where more than one semilunar cartilage was removed and in none are the results of such cases analyzed separately. Strelh (1955) reported one "double-operated" patient in his material. Springorum (1966) had in his material 51 patients in whom more than one semilunar cartilage was operated. Leuschner & Weickert (1964) stated that they had only 2 "double-operated" patients.

#### *Own results*

Here an account is given of 19 patients in whom 2 different semilunar cartilages were operated, either at the same operation or on two different occasions, in the same or in both knees. These patients were separated from the main material in order to make it as homogeneous as possible. Table 61 shows the grouping of the "double-operated" patients, with regard to the combined results. In the knee in the *Fair* group both semilunar cartilages were operated on the same occasion 20 years after the onset of the symptoms. The observation period was 8 years. The patient's disorder was almost entirely localized in the lateral side, where roentgenologic changes of type II were found. The patient had only moderate subjective complaints and objective symptoms.

On account of the character of the material, the results of these observations cannot be treated in the same way as in the main material. However, the following observation may be pointed out. No significant differences in the frequency of unsatisfactory combined results were found on comparing "double-operated", partially meniscectomized, and totally meniscectomized knees.

## CHAPTER VII

### Re-operations

In the dispute between the advocates of total meniscectomy and the adherents to partial meniscectomy, re-operations have also been used as an argument. It has, thus, been stated that after partial meniscectomy a new rupture of the remaining semilunar cartilage occurs only in about 0.5—1.0 per cent of the cases, while the risk for a new rupture after total meniscectomy is 3.0—5.0 per cent (Böhler 1955). Streli (1955) stated that in his material of 82 partially meniscectomized patients, and with an observation period of between 18 and 25 years, there was no case of relapse.

On the other hand, authors who advocate total extirpation of the semilunar cartilage maintain that a new rupture is rather usual after partial meniscectomy in the residual part of the cartilage, as sometimes also occurs after total meniscectomy (Andresen 1937, Stumpfegger 1940, Schaefer 1953, Mandl 1954, Schilling 1963, Springorum 1966). Scheibe (1963) reported that among 127 total meniscectomies recurrence occurred in only 2 cases (1.5 per cent).

#### *Own results*

In this material, consisting of 480 meniscectomized and followed-up patients, there were 5 cases or 1.04 per cent where a new operation on a previously operated semilunar cartilage was necessitated. Of these five patients one had previously undergone partial resection of the semilunar cartilage, and in four total meniscectomy had been performed at the first operation. The percentage of a rupture of the "regenerate" after total meniscectomy, i. e. 0.9 per cent, diverged from that reported by Böhler.

## CHAPTER VIII

### General discussion

Operation on account of injuries of the semilunar cartilage in the knee tends to become more usual. The possibility of verifying the clinical diagnosis by means of arthrography is probably one of the reasons which contributed towards this development. The existence of several reports of a varying, but nonetheless unambiguous, frequency of roentgenologic osteoarthritis and unsatisfactory combined results after meniscectomy, gives rise to the question whether meniscectomy is an entirely safe and invariably necessary operation.

Access to a fairly large material of meniscectomies and the results of a follow-up investigation performed personally by the author made it possible to provide statistically verified data and thus, increase our knowledge of the fate of the meniscectomized knee in several respects. The following main questions put in the introduction can now be answered.

#### 1. TO WHAT EXTENT DOES ROENTGENOLOGIC OSTEO- ARTHRITIS OCCUR AFTER MENISCECTOMY?

A significantly higher frequency of different signs of degenerative arthritis in the operated than in the nonoperated control knee is clearly demonstrated in this investigation. Thus, when the different signs of osteoarthritis are allocated to four groups it is found that patients with pronounced or severe roentgenologic signs of osteoarthritis in the operated knee represent 10.8 per cent of all totally meniscectomized knees. In the nonoperated knees the frequency of osteoarthritis was only 0.9 per cent. The frequency of roentgenologic signs of osteoarthritis in the meniscectomized knee has been reported to vary between 6.8 per cent (Rothascher

1960) and 40 per cent (Efskind 1939). In general, a substantially higher frequency of osteoarthritis in the operated knee has been reported than that observed in this material. Thus, besides Efskind, who has already been mentioned, Nitter (1946) reported a frequency of 34.3 per cent, and Franke (1966) a frequency of osteoarthritis in the operated knee of 38.8 per cent.

### *Conclusions*

Different roentgenologic signs of osteoarthritis occur in a significantly higher frequency after meniscectomy in the operated knee compared with the nonoperated control knee in the same patients. The frequency of pronounced or severe osteoarthritis in the operated knee is 10.8 per cent<sup>9)</sup> of all the totally meniscectomized knees. This relatively low frequency of knees with a considerable degree of osteoarthritis can hardly lead to the conclusion that one should abstain from removing a ruptured semilunar cartilage in the knee, despite the fact that osteoarthritis in the nonoperated knee was observed in only 0.9 per cent of the cases. No certain information exists on the extent of osteoarthritis which can occur in knees with an injured semilunar cartilage that is not operated.

## 2. TO WHAT EXTENT DO SUBJECTIVE COMPLAINTS, OBJECTIVE FINDINGS AND UNSATISFACTORY COMBINED RESULTS OCCUR AFTER MENISCECTOMY?

Subjective complaints in the meniscectomized knee occurred somewhat less frequently than roentgenologic findings in this material. There were 8.6 per cent of the patients who had distinct subjective complaints. The degree of subjective complaints was not always in agreement with the degree of roentgenologic findings. Thus, patients with substantial subjective complaints could be entirely without signs of roentgenologic osteoarthritis and vice versa.

The frequency of subjective complaints reported by different authors varies considerably. These variations are probably due to differences in the way the data were collected. If the frequencies obtained in the pre-

<sup>9)</sup> see footnote page 30

sent material are compared with those reported by authors who, as in this material, obtained their information by means of personal interrogation (Birgfeld 1928, Aleman & Friberg 1934, Saugmann-Jensen 1963, Franke 1966), then, the frequencies of subjective complaints in the material under review are somewhat lower than those earlier reported.

The frequency of objective findings was still lower than that for subjective complaints and for roentgenologic findings. When the group *Excellent* for subjective complaints is compared with the group *Normal* for objective findings the frequencies are 62.3 per cent and 80.2 per cent respectively. Patients with objective findings could be entirely without signs of roentgenologic osteoarthritis or subjective complaints or vice versa.

There are very few other authors who have reported their results for objective findings separately. Usually these are evaluated together with the subjective complaints. Normal findings were reported by Efskind (1939) only in 40 per cent of his cases, whereas Saugmann-Jensen (1963) reported 70 per cent normal objective findings in his series.

If the roentgenologic findings, subjective complaints and objective symptoms were taken together, in order to estimate the combined total results, then 7.3 per cent of the operated knees gave unsatisfactory results of groups *Fair* and *Poor*.

Despite the fact that the classification used by several authors is in general similar to that used for the present material, reported results are largely divergent. Thus, Dengler (1938) reported unsatisfactory combined results in 33.8 per cent of the patients, and Tapper & Hoover (1969) in 32.0 per cent, on the other hand, Streli (1955) had only 1.2 per cent of cases with unsatisfactory results, and Springorum (1966) 1.3 per cent.

In the present material the frequency of unsatisfactory combined results was significantly higher for women than for men. Similar observations have also been reported by other authors, but only Tapper & Hoover found existing differences to be statistically significant.

### Conclusions

The frequency of both subjective complaints and objective symptoms was lower than that of the roentgenologic findings, and this affects the combined results to some extent. Thus, there were 7.3 per cent of unsatisfactory combined results compared with 10.8 per cent of roentgenologic osteoarthritis in the meniscectomized knees. It is further evident that the combined results are influenced by the sex of the patients. Women show a significantly higher frequency of unsatisfactory combined results than men.

1960) and 40 per cent (Efskind 1939). In general, a substantially higher frequency of osteoarthritis in the operated knee has been reported than that observed in this material. Thus, besides Efskind, who has already been mentioned, Nitter (1946) reported a frequency of 34.3 per cent, and Franke (1966) a frequency of osteoarthritis in the operated knee of 38.8 per cent.

### *Conclusions*

Different roentgenologic signs of osteoarthritis occur in a significantly higher frequency after meniscectomy in the operated knee compared with the nonoperated control knee in the same patients. The frequency of pronounced or severe osteoarthritis in the operated knee is 10.8 per cent<sup>9)</sup> of all the totally meniscectomized knees. This relatively low frequency of knees with a considerable degree of osteoarthritis can hardly lead to the conclusion that one should abstain from removing a ruptured semilunar cartilage in the knee, despite the fact that osteoarthritis in the nonoperated knee was observed in only 0.9 per cent of the cases. No certain information exists on the extent of osteoarthritis which can occur in knees with an injured semilunar cartilage that is not operated.

## 2. TO WHAT EXTENT DO SUBJECTIVE COMPLAINTS, OBJECTIVE FINDINGS AND UNSATISFACTORY COMBINED RESULTS OCCUR AFTER MENISCECTOMY?

Subjective complaints in the meniscectomized knee occurred somewhat less frequently than roentgenologic findings in this material. There were 8.6 per cent of the patients who had distinct subjective complaints. The degree of subjective complaints was not always in agreement with the degree of roentgenologic findings. Thus, patients with substantial subjective complaints could be entirely without signs of roentgenologic osteoarthritis and vice versa.

The frequency of subjective complaints reported by different authors varies considerably. These variations are probably due to differences in the way the data were collected. If the frequencies obtained in the pre-

<sup>9)</sup> see footnote page 30

sent material are compared with those reported by authors who, as in this material, obtained their information by means of personal interrogation (Birgfeld 1928, Aleman & Friberg 1934, Saugmann-Jensen 1963, Franke 1966), then, the frequencies of subjective complaints in the material under review are somewhat lower than those earlier reported.

The frequency of objective findings was still lower than that for subjective complaints and for roentgenologic findings. When the group *Excellent* for subjective complaints is compared with the group *Normal* for objective findings the frequencies are 62.3 per cent and 80.2 per cent respectively. Patients with objective findings could be entirely without signs of roentgenologic osteoarthritis or subjective complaints or vice versa.

There are very few other authors who have reported their results for objective findings separately. Usually these are evaluated together with the subjective complaints. Normal findings were reported by Efskind (1939) only in 40 per cent of his cases, whereas Saugmann-Jensen (1963) reported 70 per cent normal objective findings in his series.

If the roentgenologic findings, subjective complaints and objective symptoms were taken together, in order to estimate the combined total results, then 7.3 per cent of the operated knees gave unsatisfactory results of groups *Fair* and *Poor*.

Despite the fact that the classification used by several authors is in general similar to that used for the present material, reported results are largely divergent. Thus, Dengler (1938) reported unsatisfactory combined results in 33.8 per cent of the patients, and Tapper & Hoover (1969) in 32.0 per cent; on the other hand, Strelh (1955) had only 1.2 per cent of cases with unsatisfactory results, and Springorum (1966) 1.3 per cent.

In the present material the frequency of unsatisfactory combined results was significantly higher for women than for men. Similar observations have also been reported by other authors, but only Tapper & Hoover found existing differences to be statistically significant.

### Conclusions

The frequency of both subjective complaints and objective symptoms was lower than that of the roentgenologic findings, and this affects the combined results to some extent. Thus, there were 7.3 per cent of unsatisfactory combined results compared with 10.8 per cent of roentgenologic osteoarthritis in the meniscectomized knees. It is further evident that the combined results are influenced by the sex of the patients. Women show a significantly higher frequency of unsatisfactory combined results than men.

### 3. DOES AGE AT TIME OF OPERATION AFFECT THE RESULTS?

In all total meniscectomies in the present material a significantly higher frequency of roentgenologic osteoarthritis was established in patients operated when over 41 years than in those under 41. Objective symptoms also showed a significantly higher frequency for patients operated when over 41, while, on the other hand, subjective complaints did not show any significant difference in relation to age at operation. The frequency of unsatisfactory combined results was significantly higher for patients operated when over 41 years than for those under 41.

A higher frequency of roentgenologic osteoarthritis in elderly patients at the time of the operation was reported by Scheiße (1963) and Herschmann (1965) among other investigators. A higher frequency of subjective complaints in operated patients of advanced age was reported by MacAusland (1931) and Saugmann-Jensen (1963). Higher frequency of unsatisfactory combined results for older patients at operation has been reported by several authors (Raess 1930, Meier 1933, Degler 1938, Scheiße 1963, Herschmann 1965). Many of these authors consider that injuries of the semilunar cartilage in patients over 40—45 should not be operated unless the intensity of the symptoms makes the intervention absolutely necessary.

As part of the investigation, meniscectomized knees with preoperative roentgenologic osteoarthritis or demonstrable osteoarthritis at operation were excluded from the total material, in order to ascertain the effect of the operation on a more homogeneous material. When the remaining meniscectomies are correlated with age at operation there is no significant difference, between patients operated when either over 41 or under 41, with regard to the frequency of roentgenologic signs of osteoarthritis or of unsatisfactory combined results. This is in agreement with the statement that there is no difference between older and younger operated patients with regard to the combined results (Nitter 1946, Lagergren 1953, Barfod & Biering 1956, Monn 1964, Huckell 1965). Litchman et al. (1966) reported "Excellent" combined results in a series where all patients were at least 60 years old at time of operation.

#### *Conclusions*

The statement that ■ meniscectomy should not be performed on persons of advanced age must be regarded as too far-reaching. There is, however, reason to be more restrictive about operating on elderly patients if

roentgenologic osteoarthritis is present already preoperatively. If this is not the case, then there does not seem to be any reason why a diagnosed injury of the semilunar cartilage should not be operated in elderly patients, for the same indications as those for younger patients.

#### 4. IS THE LENGTH OF THE LATENCY PERIOD OF ANY IMPORTANCE FOR THE RESULTS AFTER MENISCECTOMY?

The length of the latency period had no significant influence on any of the recorded findings or on the combined results in the present material.

With regard to the reports of several authors who in view of their observations recommend operation as early as possible (Strahlman 1921, Birgfeld 1928, MacAusland 1931, Meier 1933, Dengler 1938, Nitter 1946, Streli 1955, Barfod & Bierring 1956, Scheibe 1963, Kuhnel 1964, Leuschner & Weickert 1964, Huckell 1965, Herschmann 1965, Mohing 1966, Franke 1966, Gear 1967, Pelzl & Rueff 1969), a longer latency period was expected to give rise to a higher frequency of roentgenologically demonstrable osteoarthritis and unsatisfactory late results. However, in the present material this was not the case, which is in agreement with the reports of other authors (Raess 1930, Spira 1933, Andersson 1934, Efskind 1939, Sjøvall 1942, Saugmann-Jensen 1963, Monn 1964, Allegrini & Dell'Orto 1965, Jackson 1968, Tapper & Hoover 1969). The significance of the observed results has been verified statistically in the present series and only in two earlier works (Jackson 1968, Tapper & Hoover 1969).

Nor did the length of the latency period affect the obtained results when the cases with preoperative signs of roentgenologic osteoarthritis or osteoarthritis diagnosed at operation were excluded.

#### *Conclusions*

If the clinical and roentgenologic diagnosis of ruptured semilunar cartilage is uncertain, there is no reason to decide on an early operation of an exploratory character. The operation can be postponed until the internal derangement of the knee is further manifested, for example, by repeated locking or swelling, since the risk of higher frequency of osteoarthritic changes is not thereby significantly increased.

## 5. DOES THE TRAUMATIC ORIGIN OF A RUPTURED SEMILUNAR CARTILAGE PLAY ANY PART IN THE RESULTS?

No significant influence on the obtained results was observed when traumatic and nontraumatic ruptures of the semilunar cartilage were correlated with the different findings following a meniscectomy. Some authors have maintained that a higher frequency of unsatisfactory results occurs after operation in cases of traumatic ruptures of the semilunar cartilage (Andersson 1934, Fuss 1951, Strelé 1955, Tapper & Hoover 1969). This observation was statistically proved in the series of Tapper & Hoover, but the present results do not verify this conception. Nor do the present results verify Springorum's (1966) view, that less satisfactory results are obtained after meniscectomy if the injury was sustained without any definite trauma. According to Springorum unsatisfactory results in such cases are due to a higher degree of degeneration in both the semilunar cartilage and the joint as a whole.

### *Conclusions*

Whether the injury of the semilunar cartilage was of traumatic origin, or no certain trauma was established, neither of these conditions was found to be of any significance for the late results following meniscectomy.

## 6. IS THE LENGTH OF THE OBSERVATION PERIOD DECISIVE FOR THE UNSATISFACTORY RESULTS OBTAINED AFTER MENISCECTOMY?

A correlation of the roentgenologic findings at the follow-up investigation with the different groups of observation periods showed a significant increase in the frequency of osteoarthritis with progressing length of the observation period. The correlation is particularly evident when observation periods over and under 24 years are compared. This is in agreement with the findings of other authors who consider that analyses of the results after meniscectomy are representative only if there is a sufficiently long observation period (Nitter 1946, Strelé 1955, Saugmann-Jensen 1963, Allegreni & Dell'Orto 1965, Mohing 1966, Jackson 1968). That the frequency of osteoarthritis increases with longer observation period may, to a certain extent, be due to the fact that osteoarthritis is more common in persons of advanced age. A higher frequency of osteo-

arthritis in the operated knee has been found, however, even in elderly patients with a shorter observation period. Moreover, when patients with preoperative osteoarthritis were excluded from the material, the frequency of osteoarthritic changes at the follow-up was still significantly higher in the groups of longer observation period. Furthermore, increasing frequency of osteoarthritis occurred also in the nonoperated knee in patients with a long observation period, but the frequency of osteoarthritis was significantly higher in the operated knee compared with the nonoperated in all the groups of observation period. These findings provide evidence that the increased frequency of osteoarthritic changes observed in patients with a long observation period was an effect of the meniscectomy rather than of the more advanced age of the patients.

Contrary to the roentgenologic findings, subjective complaints, objective findings and combined total results were not influenced significantly by the length of the observation period. Nor have other authors reported that a longer observation period had any effect on the combined late results (Brechling 1942, Barfod & Bierring 1956, Herschmann 1965).

### *Conclusions*

*A material of meniscectomized patients is considered representative if there is a sufficiently long observation period. In respect of roentgenologic findings the results of the present investigation confirm this statement. The most accurate conception of the importance of an observation period for the late results after meniscectomy would be obtained, however, if the same material of meniscectomies was followed up on different occasions at intervals, for example of 5—10 years.*

## 7 ARE THE LATE RESULTS AFTER MENISCECTOMY INFLUENCED BY ANY OTHER FACTORS?

*a Preoperative clinical findings: effusion, lockings, haemarthrosis or a combination of these, have not been shown in this investigation to affect significantly the late results. Barfod & Bierring (1956) stated that especially Anglo-American authors consider that osteoarthritis after meniscectomy is related to preoperative clinical findings rather than to the operation itself. These authors point out, however, that in their own material there was no correlation between preoperative clinical findings and development of degenerative osteoarthritis after meniscectomy.*

## 5. DOES THE TRAUMATIC ORIGIN OF A RUPTURED SEMILUNAR CARTILAGE PLAY ANY PART IN THE RESULTS?

No significant influence on the obtained results was observed when traumatic and nontraumatic ruptures of the semilunar cartilage were correlated with the different findings following a meniscectomy. Some authors have maintained that a higher frequency of unsatisfactory results occurs after operation in cases of traumatic ruptures of the semilunar cartilage (Andersson 1934, Fuss 1951, Streli 1955, Tapper & Hoover 1969). This observation was statistically proved in the series of Tapper & Hoover, but the present results do not verify this conception. Nor do the present results verify Springorum's (1966) view, that less satisfactory results are obtained after meniscectomy if the injury was sustained without any definite trauma. According to Springorum unsatisfactory results in such cases are due to a higher degree of degeneration in both the semilunar cartilage and the joint as a whole.

### *Conclusions*

Whether the injury of the semilunar cartilage was of traumatic origin, or no certain trauma was established, neither of these conditions was found to be of any significance for the late results following meniscectomy.

## 6. IS THE LENGTH OF THE OBSERVATION PERIOD DECISIVE FOR THE UNSATISFACTORY RESULTS OBTAINED AFTER MENISCECTOMY?

A correlation of the roentgenologic findings at the follow-up investigation with the different groups of observation periods showed a significant increase in the frequency of osteoarthritis with progressing length of the observation period. The correlation is particularly evident when observation periods over and under 24 years are compared. This is in agreement with the findings of other authors who consider that analyses of the results after meniscectomy are representative only if there is a sufficiently long observation period (Nitter 1946, Streli 1955, Saugmann-Jensen 1963, Allegreni & Dell'Orto 1965, Mohing 1966, Jackson 1968). That the frequency of osteoarthritis increases with longer observation period may, to a certain extent, be due to the fact that osteoarthritis is more common in persons of advanced age. A higher frequency of osteo-

arthritis in the operated knee has been found, however, even in elderly patients with a shorter observation period. Moreover, when patients with preoperative osteoarthritis were excluded from the material, the frequency of osteoarthritic changes at the follow-up was still significantly higher in the groups of longer observation period. Furthermore, increasing frequency of osteoarthritis occurred also in the nonoperated knee in patients with a long observation period, but the frequency of osteoarthritis was significantly higher in the operated knee compared with the nonoperated in all the groups of observation period. These findings provide evidence that the increased frequency of osteoarthritic changes observed in patients with a long observation period was an effect of the meniscectomy rather than of the more advanced age of the patients.

Contrary to the roentgenologic findings, subjective complaints, objective findings and combined total results were not influenced significantly by the length of the observation period. Nor have other authors reported that a longer observation period had any effect on the combined late results (Brechling 1942, Barfod & Bierring 1956, Herschmann 1965).

### *Conclusions*

A material of meniscectomized patients is considered representative if there is a sufficiently long observation period. In respect of roentgenologic findings the results of the present investigation confirm this statement. The most accurate conception of the importance of an observation period for the late results after meniscectomy would be obtained, however, if the same material of meniscectomies was followed up on different occasions at intervals, for example of 5—10 years.

## 7 ARE THE LATE RESULTS AFTER MENISCECTOMY INFLUENCED BY ANY OTHER FACTORS?

a *Preoperative clinical findings* effusion, lockings, haemarthrosis or a combination of these, have not been shown in this investigation to affect significantly the late results. Barfod & Bierring (1956) stated that especially Anglo-American authors consider that osteoarthritis after meniscectomy is related to preoperative clinical findings rather than to the operation itself. These authors point out, however, that in their own material there was no correlation between preoperative clinical findings and development of degenerative osteoarthritis after meniscectomy.

## Conclusions

The observation that the occurrence of preoperative clinical findings does not influence the late results after meniscectomy supports the conclusions drawn with regard to the latency period, namely, that the late results are not necessarily worse after long postponement before operation.

b. *Preoperative osteoarthritis*, demonstrated roentgenologically or at operation has been shown to give rise to unsatisfactory late results to a significantly greater extent. At the same time it was found at the follow-up investigation that 9 patients who did not show signs of roentgenologic osteoarthritis at the follow-up exhibited such changes preoperatively. In 12 cases, in which osteoarthritis was found at operation, there were no roentgenologic signs of such a condition at the follow-up. Similar findings have been reported by Meier (1933) and Pelzl & Ruëff (1969). A possible explanation of this "regress" of osteoarthritic changes after meniscectomy may be the removal of a disturbing agent from the joint.

## Conclusions

Preoperatively demonstrated osteoarthritis either radiologically or at operation cannot be regarded as a contraindication to meniscectomy. But such preoperative findings may require caution before operating, especially on elderly patients.

c. *Postoperative infection* was reported in the patients' records in 4.8 per cent. Other signs of postoperative complications, such as effusion in the joint, prolonged for more than 3 weeks, or haemarthrosis were recorded rarely in this series. When they did occur there was no significant deterioration in the late results after meniscectomy. According to Efskind (1939), one could believe that prolonged postoperative effusion would cause a higher frequency of unsatisfactory results. This is not verified by the present material.

## Conclusions

Postoperative complications need not necessarily cause a higher frequency of unsatisfactory results.

d. *Postoperative muscular training* in totally meniscectomized patients exerted no significant influence on the late results. However, when patients with preoperative osteoarthritis, diagnosed radiologically or at operation,

ration, are excluded from the material, a significantly higher frequency of osteoarthritis and unsatisfactory combined results is found in patients who did not have postoperative muscular training compared with those who did. A significantly higher frequency of roentgenologic osteoarthritis occurred in patients with total meniscectomy where *postoperative fixation* was applied, compared with those where it was not.<sup>10)</sup> On the other hand, postoperative fixation was not found to have any significant effect on the combined results. The same conditions were prevalent also when patients with preoperative osteoarthritis were excluded from the total material.

### Conclusions

The results reported above indicate that physiotherapy and especially muscular training should be introduced as early as possible after a meniscectomy. This is at present a generally accepted routine procedure in the postoperative treatment of meniscectomized patients.

c. Patients who were allowed to *bear weight* on the operated leg first after the 2nd postoperative week showed a significantly higher frequency of roentgenologic osteoarthritis<sup>11)</sup> and unsatisfactory combined results than patients starting weight bearing earlier. Postoperative weight bearing at a later stage may be a routine measure applied by some surgeons. It is probable, however, that patients with preoperative osteoarthritis, diagnosed radiologically or at operation, were not allowed to start weight bearing until later after the operation. This assumption is supported by the fact that no significant differences in respect of either earlier or later weight bearing were found when all the patients with preoperative osteoarthritis were excluded from the material of totally meniscectomized knees.

Nelson (1968) reported better results for patients who were allowed to bear weight already after 3—4 days, though with the knee immobilized with a splint for 2 weeks, compared with those who only started weight bearing after 8—10 days.

### Conclusions

Starting weight bearing at an earlier or later stage postoperatively did not seem to influence either the roentgenologic findings or the combined results when patients with diagnosed osteoarthritis already at the time of the operation were excluded from the total material.

<sup>10—11)</sup> see footnote page 41

f. Prolonged postoperative hospitalization seemed to be connected with a higher frequency of unsatisfactory combined results, but the increased frequency was apparently linked with patients who had osteoarthritic changes in the knee already at the time of the operation. Evidently for this reason the hospitalization time was prolonged for such patients.

g. The type of occupation after meniscectomy does not seem to influence the late results. Patients who performed heavy work that involved knee strain did not show higher frequency of osteoarthritic changes in the knee or of unsatisfactory late results compared with patients engaged in lighter work. In this material only 8 patients stated that they had had to change to lighter work because of difficulties with the operated knee. Four of these patients reported at the follow-up that they had only slight subjective complaints. Raess (1930) and Meier (1933) also stated that the type of work did not influence the postoperative results.

#### Conclusions

As might be expected, the degree of the occupational strain on the knee after meniscectomy does not appear to affect the results. Heavier work, requiring greater knee strain, did not cause a higher frequency of osteoarthritis or of unsatisfactory combined results. Consequently, there is no reason to advise a patient to change to lighter work after meniscectomy.

h. Patients who were older at the follow-up investigation showed a significantly higher frequency of osteoarthritis, objective symptoms and unsatisfactory combined results compared with younger patients. There was no difference in the frequency of subjective complaints between older and younger patients. In respect of roentgenologic osteoarthritis and objective symptoms the significantly higher frequency observed in older patients was associated with a shorter observation period, which was not the case for the combined results. In the present material the frequency of degenerative arthritis increased with advancing age also in the operated knee. However, the frequency of osteoarthritic changes in all the age groups at the follow-up was significantly higher in the operated than in the nonoperated knee.

#### Conclusions

It is clear that the older the patient the more liable he will be to osteoarthritic changes in his knees. It appears, however, that a meniscectomized

knee is affected by osteoarthritis to a still greater extent than a non-meniscectomized knee. This has also been pointed out earlier (Jackson 1968).

#### 8. SHOULD A RUPTURED SEMILUNAR CARTILAGE BE PARTIALLY OR TOTALLY REMOVED?

In the present material there were only 21 knees where a partial meniscectomy was performed. These were also classified in the same way as the totally meniscectomized knees, namely, in different groups depending upon the degree of the roentgenologic findings, subjective complaints, objective findings, and in respect of the combined results. When the partially meniscectomized knees were compared statistically with the totally meniscectomized there were no significant differences in the frequency of roentgenologic osteoarthritis, the subjective complaints, the objective symptoms, or the unsatisfactory combined results.

#### *Conclusions*

The results obtained in this material did not show any significant differences between partially and totally meniscectomized knees. Consequently, the author considers that in each individual case it should be decided which surgical method is to be preferred.

f. Prolonged *postoperative hospitalization* seemed to be connected with a higher frequency of unsatisfactory combined results, but the increased frequency was apparently linked with patients who had osteoarthritic changes in the knee already at the time of the operation. Evidently for this reason the hospitalization time was prolonged for such patients.

g. *The type of occupation* after meniscectomy does not seem to influence the late results. Patients who performed heavy work that involved knee strain did not show higher frequency of osteoarthritic changes in the knee or of unsatisfactory late results compared with patients engaged in lighter work. In this material only 8 patients stated that they had had to change to lighter work because of difficulties with the operated knee. Four of these patients reported at the follow-up that they had only slight subjective complaints.

Raess (1930) and Meier (1933) also stated that the type of work did not influence the postoperative results.

### *Conclusions*

As might be expected, the degree of the occupational strain on the knee after meniscectomy does not appear to affect the results. Heavier work, requiring greater knee strain, did not cause a higher frequency of osteoarthritis or of unsatisfactory combined results. Consequently, there is no reason to advise a patient to change to lighter work after meniscectomy.

h. Patients who were older at the follow-up investigation showed a significantly higher frequency of osteoarthritis, objective symptoms and unsatisfactory combined results compared with younger patients. There was no difference in the frequency of subjective complaints between older and younger patients. In respect of roentgenologic osteoarthritis and objective symptoms the significantly higher frequency observed in older patients was associated with a shorter observation period, which was not the case for the combined results. In the present material the frequency of degenerative arthritis increased with advancing age also in the operated knee. However, the frequency of osteoarthritic changes in all the age groups at the follow-up was significantly higher in the operated than in the nonoperated knee.

### *Conclusions*

It is clear that the older the patient the more liable he will be to osteoarthritic changes in his knees. It appears, however, that a meniscectomized

knee is affected by osteoarthritis to a still greater extent than a non-meniscectomized knee. This has also been pointed out earlier (Jackson 1968).

## 8. SHOULD A RUPTURED SEMILUNAR CARTILAGE BE PARTIALLY OR TOTALLY REMOVED?

In the present material there were only 21 knees where a *partial meniscectomy* was performed. These were also classified in the same way as the totally meniscectomized knees, namely, in different groups depending upon the degree of the roentgenologic findings, subjective complaints, objective findings, and in respect of the combined results. When the partially meniscectomized knees were compared statistically with the totally meniscectomized there were no significant differences in the frequency of roentgenologic osteoarthritis, the subjective complaints, the objective symptoms, or the unsatisfactory combined results.

### *Conclusions*

The results obtained in this material did not show *any significant differences* between partially and totally meniscectomized knees. Consequently, the author considers *that in each individual case it should be decided which surgical method is to be preferred.*

## CHAPTER IX

# Summary and general conclusions

### 1. MATERIAL

a. The material of this investigation consists of 480 out of a total of 718 patients who were operated for injuries of the semilunar cartilage during the years 1921—1960 at the Regional Hospital in Linköping, Sweden. Of these 480 patients, who were followed-up personally, and evaluated as well clinically as roentgenologically, 440 were subjected to total meniscectomy and form the main material for this investigation.

b. The mean age of the patients at the time of the operation was for the entire material  $31.9 \pm 0.46$  years and for the followed-up  $33.5 \pm 0.53$  years.

c. The sex distribution for the entire material was, females to males 1 : 7.54, and for the followed-up patients 1 : 7.27.

d. The ratio lateral to medial meniscectomies was for the entire material 1 : 4.43 and for the followed-up patients 1 : 5.08.

e. The ratio left to right operated knee was for the entire material 1 : 1.20 and for the followed-up patients 1 : 1.26.

f. Definite trauma was stated to be the cause of the injury of the semilunar cartilage in 80 per cent both in the entire and in the followed-up material.

Trauma sustained in connection with athletics was reported as the cause of the injury of the semilunar cartilage in 28 per cent.

g. Meniscectomies after a latency period of more than 6 months were performed in 45.3 per cent of the entire material and in 46.8 per cent of the followed-up patients.

h. For 199 cases (41.5 per cent) the observation period was at least 14 years and for 73 cases (15.2 per cent) it was at least 24 years.

## 2. METHODS

### a. Roentgenologic findings

When assessing the signs of osteoarthritis present on the radiographies made at the follow-up investigation, the nonoperated knee was taken as the control. The different signs of osteoarthritis in the operated and the nonoperated knee were summed up and divided into 4 groups in accordance with the degree of osteoarthritis. *Group 0*: no sign of osteoarthritis; *Group I*: signs of initial osteoarthritic changes; *Group II*: pronounced osteoarthritis; *Group III*: severe osteoarthritis.

Because of the difficulties encountered in meeting the need of objective evaluation of the radiographies and in order to obtain as safe information as possible from the results of the radiologic study, two senior radiologists were asked to evaluate the radiograms separately without consulting each other. The results of each evaluation were then analyzed separately. Despite the fact that the allocation of the material to the 4 groups of radiologic findings varied considerably in the two evaluations, the results of the statistical analyses were strikingly similar with only very few minor divergencies. This fact has been regarded as indicating a high degree of reliability in the estimation of the roentgenologic findings in the present investigation.

### b. Subjective complaints

The assessment of the subjective complaints was based on a standardized questionnaire used at the personal interrogation of all the patients. According to the information supplied by the patients concerning their complaints, the different degrees of complaints were allocated to 4 groups. *Excellent*: no complaints, *Good*: only mild complaints; *Fair*: distinct subjective complaints; *Bad*: fairly pronounced complaints.

### c. Objective clinical findings

The assessment of the objective findings was also based on a standardized investigation form. The frequency of the objective symptoms was substantially less than the frequency of the subjective complaints and the roentgenologic findings. Consequently, the objective findings were divided into only two groups. *Normal*: no, or only slight, objective symptoms. *With findings*: knees with distinct objective symptoms.

#### d. *Combined results*

Roentgenologic findings, subjective complaints and objective symptoms were combined to form 4 different groups of combined results. *Group Excellent*: none or at most, slight roentgenologic findings, subjective complaints or objective symptoms. *Group Good*: moderate findings. *Group Fair*: evident findings. *Group Poor*: pronounced roentgenologic findings, subjective complaints and objective symptoms.

### 3. ROENTGENOLOGIC RESULTS

a. A significantly higher frequency of roentgenologic osteoarthritis was shown to occur in the meniscectomized knee compared with the non-operated knee. No statistically significant difference was demonstrated between totally and partially meniscectomized knees, in respect of roentgenologic osteoarthritis. Among total meniscectomies no significant difference was found between medially and laterally operated knees, but a significantly higher frequency for women than for men. The small number of partial meniscectomies makes a detailed statistical analyses of these cases impossible. Totally meniscectomized knees were analyzed for different factors which could possibly promote arthritis.

b. A correlation of the roentgenologic findings for all followed-up meniscectomized patients with *age at time of operation* showed a significantly higher frequency of osteoarthritis in patients meniscectomized when over 41 years compared with those operated when under 41. When all the patients with preoperative osteoarthritis, diagnosed radiologically or at operation, were excluded, there were no significant differences in the postoperative roentgenologic findings between patients operated when over 41 and those operated when under 41.

c. *Latency period*, — the time that elapsed between trauma, or occurrence of symptoms, and operation, — shorter or longer than 6 months did not influence significantly the occurrence of roentgenologic signs of osteoarthritis. Nor were any significant differences observed, in respect of latency periods, between patients meniscectomized after or before the age of 41. Moreover, when cases with osteoarthritis already at time of the operation were excluded, there were not any significant differences in the frequency of roentgenologic osteoarthritis in respect of the latency period.

d. *Trauma* as cause of the rupture of the semilunar cartilage did not show any significant influence on the occurrence of roentgenologic osteoarthritis following meniscectomy.

e. *The length of the observation period* was found to be of significant importance for the occurrence of roentgenologic osteoarthritis in meniscectomized knees. When the observation period was longer, the frequency of osteoarthritis increased; the difference was especially pronounced if knees with observation periods over and under 24 years were compared. If knees with osteoarthritis already at the time of the operation are excluded from the main material of meniscectomies, there was still a significantly increased frequency of roentgenologic osteoarthritis in patients with longer observation period.

f. Furthermore, a significantly higher frequency of roentgenologic osteoarthritis was found to be present at the follow-up investigation, 1) if the patient had roentgenologically demonstrable osteoarthritis prior to operation, 2) if osteoarthritis was found at the time of operation, 3) if weight bearing was started later postoperatively<sup>12)</sup>, and 4) if at the follow-up the patient's age was over 61 years, and then especially in connection with a short observation period. With regard to the time when weight bearing was started, no significant differences occurred if all the cases with preoperative osteoarthritis, diagnosed radiologically or at time of operation, were excluded.

g. *Clinical findings prior to operation*, such as lockings, effusion and haemarthrosis or a combination of these, as well as *postoperative complications* — prolonged effusion, haemarthrosis or signs of infection — did not show any significant influence on the frequency of roentgenologic osteoarthritis in the meniscectomized knee.

h. Patients, where *muscular training* was applied postoperatively, developed a significantly lower frequency of osteoarthritis compared with patients who had not received muscular training, if all cases with osteoarthritis at the time of operation were excluded.

In contrast to this, patients where *postoperative fixation* had been applied had a significantly higher frequency of osteoarthritis compared with patients treated without postoperative fixation<sup>13)</sup>. But this holds only for all totally meniscectomized patients, and not for those with no preoperative signs of osteoarthritis, where the frequency is lower.

<sup>12—13)</sup> see footnote page 41

i. *Postoperative heavier work*, which involved also more knee strain, compared with work requiring less knee strain, did not influence significantly the frequency of roentgenologic osteoarthritis in the meniscectomized knee.

#### 4. RESULTS FOR SUBJECTIVE COMPLAINTS

a. When comparing males and females with regard to the different subjective complaints either separately or in groups, women had a significantly higher frequency of subjective complaints than men.

Nor were there any significant differences, with regard to subjective complaints, between partially and totally meniscectomized knees.

b. Contrary to what was the case with roentgenologic findings, there were no significant differences in the frequency of subjective complaints, between totally meniscectomized knees, whether these had been operated when the patient was under or over 41 years.

c. Nor was the length of the *latency period* of any significance for the frequency of subjective complaints.

d. *Trauma* as the cause of rupture of the semilunar cartilage did not have any significant influence on the frequency of subjective complaints after total meniscectomy.

e. The length of the *observation period* was not found to have any significant effect on the subjective complaints.

f. Among other factors, a later start with weight bearing showed a significantly higher frequency of subjective complaints.

#### 5. RESULTS FOR OBJECTIVE FINDINGS

a. The objective findings showed no significant difference in frequency between medially and laterally meniscectomized knees, or between men and women. Nor was there any significant difference between totally and partially meniscectomized knees with regard to the frequency of objective findings.

b. *Age at time of operation* showed a significantly higher frequency of objective findings in patients meniscectomized when over 41 years than in those under 41.

c. *Latency periods* longer or shorter than 6 months did not show any significant influence on the occurrence of objective findings.

d. *Trauma* as cause of the lesion in the semilunar cartilage did not seem to influence significantly the frequency of objective findings after total meniscectomy.

e. The length of the *observation period* did not play any significant role in the occurrence of objective findings.

f. Of the other factors, osteoarthritis at time of operation and postoperative fixation increased significantly the frequency of objective findings after total meniscectomy.

g. Later start with weight bearing and longer postoperative hospitalization showed a higher frequency of objective findings.

h. A higher frequency of objective findings was observed in patients over 61 years at time of the follow-up investigation than in those under 61. This applies especially to patients over 61 at the time of the follow-up who, at the same time, had a short observation period.

## ■ COMBINED TOTAL RESULTS

a. Differences, in the frequency of unsatisfactory combined results, between medially and laterally meniscectomized knees did not prove to be significant, here women showed a significant increase in the frequency of unsatisfactory total results compared with men.

b. No significant differences were obtained with regard to the frequency of unsatisfactory combined results when the totally meniscectomized, the partially meniscectomized and the "double-operated" knees were compared

c. The frequency of unsatisfactory combined results in totally meniscectomized patients, who at operation were older than 41 years, was significantly higher than that of younger patients. If, however, patients with

preoperative osteoarthritis were excluded from the material, no significant differences were obtained.

d. *Latency periods* over or under 6 months did not have any significant influence on the combined results for the total meniscectomies.

e. The frequency of the unsatisfactory combined results after total meniscectomy in *traumatic* and *nontraumatic* ruptures of the semilunar cartilage was not affected significantly.

f. The length of the *observation period* did not influence significantly the frequency of unsatisfactory combined results.

g. Of other factors which might possibly cause less satisfactory results, the existence of preoperative roentgenologic osteoarthritis and osteoarthritis diagnosed at time of operation deteriorated the combined total results significantly.

h. Preoperative clinical findings, postoperative complications, and postoperative fixation were not found to affect significantly the combined results after total meniscectomy.

i. If postoperative weight bearing was started later, then a significantly higher frequency of unsatisfactory combined results was observed for all the meniscectomized patients. If, however, patients with osteoarthritis at time of operation were excluded from the material no significant differences were found.

j. Postoperative muscular training gave rise to a significantly lower frequency of unsatisfactory results, if the patients who had osteoarthritis at the time of operation were excluded.

k. Patients of advanced age at the follow-up investigation showed a significantly higher frequency of unsatisfactory results.

l. The type of the postoperative occupation was not found to have any significant influence on the combined total results.

## 7. GENERAL CONCLUSIONS

Degenerative osteoarthritis occurs in a significantly higher frequency in a meniscectomized knee compared with the nonoperated control knee.

The frequency of different degrees of roentgenologic osteoarthritis in this investigation was about 10.8 per cent in the operated and 0.9 per cent in the nonoperated knee in the totally meniscectomized patients, and 9.5 per cent in the partially meniscectomized knees.

The frequency of subjective complaints and objective symptoms is lower than that of the combined total results. The frequency of roentgenologic findings is contrary higher. Apparently the low frequency of subjective complaints affect the combined total results in a higher extent than roentgenologic findings do.

*Age at time of operation* does not appear to influence the results.

*A longer latency period* does not cause worse results.

*Trauma as an aetiological factor* for the rupture of the semilunar cartilage does not influence the postoperative results.

Radiological signs of osteoarthritis increase with the length of the observation period. This applies especially for observation periods exceeding 24 years.

Existence or absence of *preoperative clinical findings* does not affect the results.

*Roentgenologic osteoarthritis prior to operation* gives rise to increased frequency of unsatisfactory results.

*Postoperative complications* need not necessarily imply a worse prognosis with regard to the late results.

*Postoperative muscular training* gives rise to substantially better results for the subsequent course.

*Postoperative fixation of the knee* decreases the frequency of late osteoarthritis.

*Early or late postoperative weight bearing* does not affect the late results.

*The type of occupation after a meniscectomy* is of no importance for the late result.

*Partial resection or total extirpation of a ruptured semilunar cartilage* does not influence the late results.

preoperative osteoarthritis were excluded from the material, no significant differences were obtained.

d. *Latency periods* over or under 6 months did not have any significant influence on the combined results for the total meniscectomies.

e. The frequency of the unsatisfactory combined results after total meniscectomy in *traumatic* and *nontraumatic* ruptures of the semilunar cartilage was not affected significantly.

f. The length of the *observation period* did not influence significantly the frequency of unsatisfactory combined results.

g. Of other factors which might possibly cause less satisfactory results, the existence of preoperative roentgenologic osteoarthritis and osteoarthritis diagnosed at time of operation deteriorated the combined total results significantly.

h. Preoperative clinical findings, postoperative complications, and postoperative fixation were not found to affect significantly the combined results after total meniscectomy.

i. If postoperative weight bearing was started later, then a significantly higher frequency of unsatisfactory combined results was observed for all the meniscectomized patients. If, however, patients with osteoarthritis at time of operation were excluded from the material no significant differences were found.

j. Postoperative muscular training gave rise to a significantly lower frequency of unsatisfactory results, if the patients who had osteoarthritis at the time of operation were excluded.

k. Patients of advanced age at the follow-up investigation showed a significantly higher frequency of unsatisfactory results.

l. The type of the postoperative occupation was not found to have any significant influence on the combined total results.

## 7. GENERAL CONCLUSIONS

Degenerative osteoarthritis occurs in a significantly higher frequency in a meniscectomized knee compared with the nonoperated control knee.

The frequency of different degrees of roentgenologic osteoarthritis in this investigation was about 10.8 per cent in the operated and 0.9 per cent in the nonoperated knee in the totally meniscectomized patients, and 9.5 per cent in the partially meniscectomized knees.

The frequency of subjective complaints and objective symptoms is lower than that of the combined total results. The frequency of roentgenologic findings is contrary higher. Apparently the low frequency of subjective complaints affect the combined total results in a higher extent than roentgenologic findings do.

*Age at time of operation* does not appear to influence the results.

*A longer latency period* does not cause worse results.

*Trauma* as an aetiological factor for the rupture of the semilunar cartilage does not influence the postoperative results.

*Radiological signs of osteoarthritis* increase with the length of the observation period. This applies especially for observation periods exceeding 24 years.

*Existence or absence of preoperative clinical findings* does not affect the results.

*Roentgenologic osteoarthritis prior to operation* gives rise to increased frequency of unsatisfactory results.

*Postoperative complications* need not necessarily imply a worse prognosis with regard to the late results.

*Postoperative muscular training* gives rise to substantially better results for the subsequent course.

*Postoperative fixation* of the knee decreases the frequency of late osteoarthritis.

*Early or late postoperative weight bearing* does not affect the late results.

*The type of occupation* after a meniscectomy is of no importance for the late result.

*Partial resection or total extirpation* of a ruptured semilunar cartilage does not influence the late results.

## INTRODUCTION

The blood supply of the femoral head has long been the subject of anatomical studies on cadavers and specimens (20, 33, 11, 31, 29, 14, 10, 26, 25). These examinations have shown that the femoral head is supplied by branches of the medial circumflex artery and its posterior collum branch. The supply of the femoral head is maintained mostly by the superior retinacular artery, the termination of the posterior collum branch. The inferior retinacular and ligamentum teres arteries play a smaller part but may in some measure compensate for a disturbance of the circulation in the superior retinacular artery (25). In Fig. 1 the vessels to and around the caput are shown schematically. The arteries are indicated by numbers which are also used in the arteriograms below.

Clinical investigation of the blood supply of the femoral head in living persons was stimulated by the attempt to predict the viability of the head after neck fracture. A reliable prognosis would make possible proper treatment of the fracture in each individual case. A solution to the problem has been sought either by direct demonstration of the vascular pattern of the hip by arteriography or by estimation of the circulatory state of the head carried out with several methods; the best known and/or important ones may be mentioned.

*Intraosseous venography* (12, 32) is based on the examination of the venous drainage from the femoral head after injection of contrast material into the head. Demonstration of one or several draining veins is presumed to indicate intact arterial supply of the caput, whereas the lack of venous filling suggests arterial damage. *Radioisotopes* are injected intravenously or into the femoral head in order to study the circulation to or from it (31, 6, 15, 7, 13). The circulatory state of the caput is calculated and its viability predicted from the access of the isotope into the general circulation or uptake in

All the tests mentioned, used for prediction of the viability of the caput after neck fracture, are not, however, appropriate for study of the arteries themselves, which is possible by arteriography. This seems to be the method of choice for direct studies of the arteries in both normal, unaffected hips and in cases with fracture and femoral head necrosis.

Angiography in unaffected hips has already been carried out to a limited extent by Müssbichler (19), Hipp (10), and Brugger (8). Based on the findings of these examinations, arrested and/or delayed circulation in the posterior collum branch could be disclosed in neck fractures by Müssbichler (19). These findings were later confirmed by other authors (10, 8, 9, 17). Brunner et al. (9) showed additionally a close relationship between arrested circulation and development of femoral head necrosis as well as a relationship between normal circulation and healing of the fracture without necrosis. Femoral head necrosis has also been the subject of angiographic examinations. Müssbichler (19) noted delayed circulation in the posterior collum branch in 3 out of 4 cases examined. Lange and Hipp (16) reported on 6 cases and described a great variety of findings such as smallness, shortness, incomplete filling, and non-filling of the posterior collum branch or the femoral head vessels.

In the above-mentioned angiographic investigations many interesting questions were, however, left unanswered. The vessels of the unaffected hips, only examined as a complement to the studies of the vascular condition in affected hips, were not examined with regard to vascular details. Furthermore, in neck fractures the circulatory lesions were not studied in relation either to the type of dislocation or to reduction of the fracture. Systematic angiographic studies of fractures after nailing have not been carried out either. Angiographic studies of patients with pertrochanteric fracture or necrosis of the femoral head are restricted to only a few cases (19, 16, 10) from which, so far, no definite conclusions can be drawn.

Recent developments in angiographic techniques, such as the use of catheters, serial angiography with an automatic filmchanger, and the subtraction method (36) have made possible examination of the hip in different positions and have permitted far more reliable demonstration of the arterial circulation. These methods have to a great extent been used in the present investigation, the aims of which may be defined as follows:

the caput. Both intraosseous venography and the radioisotope methods are, as is obvious from the reports of their initiators, associated with a relatively high frequency of false and/or unconclusive results concerning the reliability of the prediction of the fate of the femoral head after neck fracture.

Direct registration of the circulatory state is possible by *intraosseous pressure* measurement *ad modum* Arnoldi and Linderholm (2) and by the use of the *oxygen tension test* devised by Woodhouse (34). Pulseless tracings from the femoral head as well as the lack of a rise in  $pO_2$  in the caput after inhalation of 100 % oxygen is presumed to indicate avascularity. However, no prospective studies of these two methods have been published yet.

FIG. 1. Schematic drawing of the arteries to and around the femoral head 1 medial circumflex art., 2. posterior collum branch, 3. superior retinacular art., 4 inferior retinacular art., 5 acetabular art., 5a. ligamentum teres art, 6 deep femoral art.; 7. common femoral art., 8 inferior branch of the medial circumflex art.; 9. ascending branch of the lateral circumflex art, 9a. its superior branch, 10. obturator artery.

## MATERIAL AND METHODS

Angiography was carried out in a total of 167 cases examined with one or several of the following methods:

- A. "General" arteriography (I, II, III) with injection of contrast material into the common femoral artery in a retrograde direction carried out either through a blunt Seldinger cannula, in 34 cases, or through a polyethylene catheter, in 99 cases (Fig. 2 A).
- B. "Semiselective" arteriography (I) with injection of contrast material into the common femoral artery in antegrade, i. e. in peripheral, direction. This was achieved either by use of a loop-formed Odman-Ledin catheter (21), in 26 cases, or a straight polyethylene catheter, in 3 cases (Figs. 2 A', 3 and 7 lower). For the application of methods A. and B., the femoral artery was compressed at the thigh with a pressure cuff. The contrast medium (16 and 10 ml Urografin 76 % respectively) was injected for 2—3 seconds.
- C. Selective internal iliac arteriography (I) with injection of 10 ml Urografin 76 % into the trunk of the internal iliac artery with a loop-formed, red Odman-Ledin catheter (Fig. 4), in 14 cases; nine of them were part of the case material examined by method A or B.

While methods A. and B. were used for evaluation of the vessels of the hip, C. was used in order to study whether and to what extent the internal iliac artery contributes to the blood supply of the femoral head.

- A. To study the vascular pattern in healthy hips with regard to frequency of filling, origin, course, and ramification of the arteries most important for the nutrition of the hip joint and the femoral head in particular (I).
- B. To study medial neck and pertrochanteric fractures angiographically with reference to the type of vascular lesion, their incidence, and relation to fracture dislocation, fracture reduction, and osteosynthesis; and furthermore to correlate the vascular findings from fresh and operated fractures with the fate of the caput as regards necrosis (II).
- C. To study the type and occurrence of vascular changes in necrosis of the femoral head after medial neck fracture (III).

FIG. 1 Subtraction angiogram from a semiselective examination illustrating the filling of the femoral head vessels except the superior retinacular art., the demonstration of which was, for some reason, not possible. Posterior collum branch (2), inferior retinacular art. (4), acetabular (5), and hg. teres art. (5 a) generated by the acetabular branches (small arrows) of the obturator and medial circumflex arts. respectively.

FIG. 2. One case examined with both general (A) and semiselective (A') arteriography. In (A) gluteal branches (small arrows) are superimposed on the femoral head and its vessels, particularly the superior retinacular artery (3) whereas in (A') the filling is limited to the external iliac art. and its branches only. Posterior collum branch (2) originating in the bifurcation (1) of the medial circumflex artery together with the inferior branch (8); ascending branch of the lateral circumflex art. (9).

In the 34 cases in which a Seldinger cannula was used, 20 ml Diodon 50 % was injected and 4 exposures were taken over about 12 seconds. The examination with the cannula was performed in a-p projection with the hip in inward or outward rotation. In the remainder, in which a catheter was used, the examination was performed with injections of 10 or 16 ml Urografin 76 %, serial exposures, 1 per second for 15 seconds, and the subtraction method for evaluation of the angiograms.

In order to show the great range of individual variations, the diameters of the most important arteries were measured with the aid of a magnifying glass with a built-in mm scale.

## RESULTS

### *Normal hips (I)*

The vessels of the clinically and roentgenologically unaffected hips were studied in angiograms from 106 examinations in a total of 97 cases. Ninety-two were examined with general or semiselective arteriography and 14 cases with selective internal iliac arteriography; 9 of the latter were part of the material also studied with general arteriography.

The present investigation concerned evaluation of the anatomy of those arteries which directly or indirectly participate in the blood supply of the hip joint and of the femoral head in particular. They comprise branches of the medial and lateral circumflex arteries such as the posterior collum branch, the acetabular, ligamentum teres, inferior, and superior retinacular arteries, the ascending branch of the lateral circumflex artery, as well as arterial communications from the internal iliac artery to the femoral head (Figs. 1—7).

The results from general and semiselective arteriography were practically equal as regards the frequency of filling of the femoral head vessels, except for the acetabular artery in which the filling varied somewhat according to the method (see below).

The arteries of the hip known from the studies of anatomists (Fig. 1) could, in principle, be confirmed in living subjects by the present investigation (Figs. 2 and 3). Additionally, the present study revealed great individual variation as regards location of the origin, course and diameter of the vessels and their filling frequency. The most important variations concerned anomalies of the posterior collum branch such as hypoplasia in 3 cases (Fig. 5) and non-filling from the medial circumflex artery in 11 cases (Fig. 6), the latter was frequently found bilaterally. In 2 of these 11 cases, an ectopic origin of the posterior collum branch from the inferior gluteal artery was disclosed (Fig. 7), whereas in the remaining 9 cases the branch was not filled. The superior retinacular and acetabular arteries also varied individually in size and the incidence of their filling. The

FIG. 4. Subtraction angiograms from selective internal iliac arteriography in different phases. The posterior collum branch (2) fills retrogradely via an anastomosis from the inferior gluteal art. (11), the medial circumflex artery fills via a branch (10) from the obturator artery. Anastomosis between the superior gluteal (12) and lateral circumflex (9) arts.

### *Complications (I, II, III)*

Arteriography gave rise to thrombo-embolism in the femoral artery in one case with advanced atherosclerosis examined with a polyethylene catheter. Embolectomy was carried out and the patient recovered. In another case a transitory spasm of the external iliac artery occurred during catheterization with the loop-formed, red Ödman-Ledin catheter. The examination was interrupted and postponed until the next day, when it was successfully carried out with a polyethylene catheter without incidents. No other complications occurred.

## RESULTS

### *Normal hips (I)*

The vessels of the clinically and roentgenologically unaffected hips were studied in angiograms from 106 examinations in a total of 97 cases. Ninety-two were examined with general or semiselective arteriography and 14 cases with selective internal iliac arteriography; 9 of the latter were part of the material also studied with general arteriography.

The present investigation concerned evaluation of the anatomy of those arteries which directly or indirectly participate in the blood supply of the hip joint and of the femoral head in particular. They comprise branches of the medial and lateral circumflex arteries such as the posterior collum branch, the acetabular, ligamentum teres, inferior, and superior retinacular arteries, the ascending branch of the lateral circumflex artery, as well as arterial communications from the internal iliac artery to the femoral head (Figs. 1—7).

The results from general and semiselective arteriography were practically equal as regards the frequency of filling of the femoral head vessels, except for the acetabular artery in which the filling varied somewhat according to the method (see below).

The arteries of the hip known from the studies of anatomists (Fig. 1) could, in principle, be confirmed in living subjects by the present investigation (Figs. 2 and 3). Additionally, the present study revealed great individual variation as regards location of the origin, course and diameter of the vessels and their filling frequency. The most important variations concerned anomalies of the posterior collum branch such as hypoplasia in 3 cases (Fig. 5) and non-filling from the medial circumflex artery in 11 cases (Fig. 6), the latter was frequently found bilaterally. In 2 of these 11 cases, an ectopic origin of the posterior collum branch from the inferior gluteal artery was disclosed (Fig. 7), whereas in the remaining 9 cases the branch was not filled. The superior retinacular and acetabular arteries also varied individually in size and the incidence of their filling. The

FIG. 4. Subtraction angiograms from selective internal iliac arteriography in different phases. The posterior column branch (2) fills retrogradely via an anastomosis from the inferior gluteal art (11), the medial circumflex artery fills via a branch (10) from the obturator artery. Anastomosis between the superior gluteal (12) and lateral circumflex (9) arts.

### *Complications (I, II, III)*

Arteriography gave rise to thrombo-embolism in the femoral artery in one case with advanced atherosclerosis examined with a polyethylene catheter. Embolectomy was carried out and the patient recovered. In another case a transitory spasm of the external iliac artery occurred during catheterization with the loop-formed, red Ödman-Ledin catheter. The examination was interrupted and postponed until the next day, when it was successfully carried out with a polyethylene catheter without incidents. No other complications occurred.

superior retinacular artery could not be demonstrated in any of the 14 cases in which the posterior collum branch was anomalous. In the remainder (78 cases), it filled with a frequency of 81 %. The incidence of filling of the other femoral head vessels, not influenced by anomalies of the posterior branch, was for the inferior retinacular artery 63 % and for the acetabular artery 27 % and 40 % when examined with semiselective and general arteriography respectively. The ligamentum teres artery was demonstrated in 2 cases only. Selective filling of the internal iliac artery disclosed, in addition to an ectopic origin of the posterior collum branch (2 cases), small anastomoses from the inferior gluteal artery to the posterior collum branch in 3 out of 14 cases (Fig. 4).

Atherosclerotic changes were found in the medial circumflex artery as well as in the posterior collum branch in some cases.

FIG. 7. Upper Semiselective arteriogram showing non filling of the posterior collum branch, not derived from the medial circumflex art. (1); its inferior branch (8) is well filled. Soft tissue branches (small arrows) from the lateral circumflex art., ascending branch (9); tip of the looped catheter (K).

Lower Selective internal iliac arteriogram of the same case in different phases and positions, disclosing the ectopic origin of the posterior collum branch (2) from the inferior gluteal artery (11).

FIG. 5. Semiselective arteriography carried out by insertion of a polyethylene catheter (K) into the common femoral artery in a peripheral direction. Hypoplasia of the posterior collum branch (2) terminating in small branches (white arrows) far from the trochanteric notch. Medial circumflex art. (1).

FIG. 6. Non-filling of the posterior collum branch due to anomaly. It is not derived from the medial circumflex art (1) either in the arthrotic hip (A) or in the contralateral, healthy one (B). Good filling of the inferior branch (8) which was consistently present. Subtraction angiogram (B') illustrates the superior branch (9a) from the lateral circumflex artery—possibly replacing the posterior collum branch.

superior retinacular artery could not be demonstrated in any of the 14 cases in which the posterior collum branch was anomalous. In the remainder (78 cases), it filled with a frequency of 81 %. The incidence of filling of the other femoral head vessels, not influenced by anomalies of the posterior branch, was for the inferior retinacular artery 63 % and for the acetabular artery 27 % and 40 % when examined with semiselective and general arteriography respectively. The ligamentum teres artery was demonstrated in 2 cases only. Selective filling of the internal iliac artery disclosed, in addition to an ectopic origin of the posterior collum branch (2 cases), small anastomoses from the inferior gluteal artery to the posterior collum branch in 3 out of 14 cases (Fig. 4).

Atherosclerotic changes were found in the medial circumflex artery as well as in the posterior collum branch in some cases.

FIG. 7. *Upper* Semiselective arteriogram showing non filling of the posterior collum branch, not derived from the medial circumflex art. (1); its inferior branch (8) is well filled. Soft tissue branches (small arrows) from the lateral circumflex art., ascending branch (9), tip of the looped catheter (K).

*Lower* Selective internal iliac arteriogram of the same case in different phases and positions, disclosing the ectopic origin of the posterior collum branch (2) from the inferior gluteal artery (11).

FIG. 5. Semiselective arteriography carried out by insertion of a polyethylene catheter (K) into the common femoral artery in a peripheral direction. Hypoplasia of the posterior collum branch (2) terminating in small branches (white arrows) far from the trochanteric notch. Medial circumflex art. (1).

FIG. 6. Non-filling of the posterior collum branch due to anomaly. It is not derived from the medial circumflex art. (1) either in the arthrotic hip (A) or in the contralateral, healthy one (B). Good filling of the inferior branch (8) which was consistently present. Subtraction angiogram (B') illustrates the superior branch (9a) from the lateral circumflex artery-possibly replacing the posterior collum branch.

FIG. 9 Upper Serial angiograms of a recent neck fracture in varus position. The circulation in the posterior collum branch is arrested (arrows) and contrast material is pooling in the intact trunk of the vessel

Lower After reduction and nailing the circulation is restored and the posterior collum branch re-filled (left, arrow), nevertheless necrosis of the femoral head occurred later (right)

in it became arrested in the later arterial phase. The superior retinacular artery did not fill in any of the cases when the circulation was disturbed in the posterior collum branch whereas the other femoral head vessels were not affected.

From correlation of the circulatory conditions in the posterior collum branch with the type of dislocation of the fracture, the following results were obtained: (a) circulation was disturbed only in

## Fractures (II)

Forty-nine patients with fractures of the proximal end of the femur were examined with general arteriography. The fractures involved the medial part of the neck in 37 cases and the pertrochanteric region in 12. The examination concerned 37 cases with fresh fractures, 27 neck and 10 pertrochanteric, which were examined one to three days after the accident. Twenty-five of them (20 neck and 5 pertrochanteric fractures) were re-examined one to three weeks after nailing, and 12 (10 neck and 2 pertrochanteric fractures) were only studied after the operation.

Of the 37 cases with recent, unreduced fractures, the circulation in the posterior collum branch was normal in 19 cases and disturbed in 18. The latter comprised delayed circulation (Fig. 8) in 3 neck fractures; circulation was arrested (Figs. 9—12) in 12 neck and 3 pertrochanteric fractures. In 2 of the former the circulation was "intermittently" arrested only, i. e. the posterior collum branch was normally filled at the beginning of the arterial phase but circulation

FIG. 8. Serial angiography of a recent neck fracture without dislocation. The posterior collum branch (arrows) is well filled (left) but the circulation through it is delayed which is indicated by pooling of contrast medium in its peripheral part (right, heavy arrow)

FIG 11 *Upper* Serial angiograms of a recent malrotated petrochantetic fracture with arrested circulation (heavy arrow) in the posterior collum branch  
*Lower* After reduction of the malrotation by forced inward rotation of the leg, the circulation normalized and two branches of the superior retinacular artery also filled (arrows)

malrotated recent fractures (the findings concerned 15 neck and 3 pertrochanteric fractures), and (b) circulation was normal in 12 neck and 7 pertrochanteric fractures with malrotation present in only 3 and 1 cases respectively. The circulation was not affected by valgus or dorsal angulation up to 30 degrees.

FIG. 10. A. Serial angiogram of a fresh, malrotated neck fracture with arrested circulation (arrow) in the posterior collum branch. B. Serial angiograms after reduction of the malrotation by forced inward rotation of the leg. Now a complete filling of the posterior collum branch is obtained (B<sub>1</sub>, arrow); however, the circulation is somewhat delayed, visible from the pooling of the contrast material at the end of the arterial phase (B<sub>2</sub>, heavy arrow).

FIG 12 Serial angiogram of a recent, malrotated, pertrochanteric fracture with arrested circulation in the posterior collum branch (left, heavy arrow). After reduction and nailing (right), the circulation normalized (2) and the superior (3) and inferior retinacular (4) arteries became well filled.

FIG 13 Two cases (A, B) with pertrochanteric fractures. In both cases the posterior collum branch did not fill because of an anomaly. This condition should not be misinterpreted as a circulatory disturbance. Medial circumflex art (1), inferior branch (8), ascending branch of the lateral circumflex art. (9), branches of the inferior gluteal art (small arrows in B).

Reduction of malrotation by forced manual inward rotation of the leg was immediately followed by restitution of the circulation in the posterior collum branch (Figs. 10 and 11). This was noted in 5 cases in which the reduction manoeuvre was successful. Restitution in the posterior collum branch was accompanied by a filling of the superior retinacular artery in 2 cases.

Thirty-seven patients were examined after definitive reduction and nailing; in no case was arrested circulation observed. In the 13 cases with arrested circulation prior to operation, filling of the posterior collum branch was restored to normal in all cases (Figs. 9 and 12). However, in 4 of them, 3 neck and 1 pertrochanteric fractures, the circulation remained delayed.

Forced outward rotation of the leg also caused arrest of the circulation in the posterior collum branch in 2 pertrochanteric fractures even though they had been thoroughly reduced and nailed.

Non filling of the posterior collum branch due to an anomaly was observed in 1 neck and 2 pertrochanteric fractures (Fig. 13).

A follow-up study of 9 fresh, unreduced neck fractures with arrested circulation revealed later development of femoral head necrosis in 7 cases, whereas in the fresh fractures with normal or delayed circulation necrosis occurred in only 1 out of 9 cases. Out of the 24 neck fractures examined angiographically after nailing and followed-up, necrosis developed in 9 cases, in 2 of which the circulation had been delayed in the fresh fracture. In the remaining 15 cases, 1 with delayed and 14 with normal circulation, necrosis did not appear.

The superior retinacular artery was not filled in any of the 11 cases in which necrosis developed, whereas it had filled in 7 out of the 16 cases in which necrosis was not established at follow-up. No correlation was found between the incidence of filling of the other femoral head vessels and the ultimate fate of the caput.

Necrosis was not seen to develop in any of the 7 pertrochanteric fractures followed-up. In one of them, however, the circulation in the posterior collum branch was arrested prior to reduction.

FIG. 15 Conventional and subtraction angiograms in necrosis of the femoral head. Enlarged inferior retinacular artery (4) hypervascularizing the medial, less involved portion of the caput. Medial circumflex art. (1), posterior collum branch (2) with arrested circulation in outward rotation of the leg.

FIG. 16 Subtraction angiograms of a case with necrosis and non united fracture. Posterior collum branch (heavy arrow). The fracture area is hypervascularized (h), optimally visible in late arterial phase (right). Venous drainage indicated by small arrows.

### Necrosis (III)

An account is given of the arteriographic findings from 21 cases with necrosis of the femoral head after medial neck fracture. In agreement with previous observations (19), delayed circulation in the posterior collum branch was a frequent and typical finding evident in 13 cases (Fig. 14). Furthermore, the present examination disclosed that the superior retinacular artery did not fill in any of the cases with necrosis, indicating nutritional disturbance of the caput. On the other hand, the inferior retinacular artery was frequently enlarged (Fig. 15) and the acetabular and ligamentum teres arteries were both enlarged and more frequently filled than in the unaffected control hips. Moreover, hypervascular areas were found at the site of the old fracture and the less necrotic, medial portion of the femoral head in 14 cases (Figs. 14—16).

Rotation studies of the leg were performed in 14 cases. In inward rotation, the posterior collum branch was well filled in all cases, but circulation in it was interrupted in 4 cases when the leg was outwardly rotated by force (Figs. 15 and 17). All 4 cases were old, unhealed neck fractures which in the latter instance became malrotated.

FIG 14 Serial angiograms of a case with total necrosis of the femoral head. Good filling of the posterior collum branch (2) in which the contrast medium is pooling throughout the venous phase (*right*), vein (*v*), hypervascular area (*h*)

FIG 15. Conventional and subtraction angiograms in necrosis of the femoral head. Enlarged inferior retinacular artery (4) hypervascularizing the medial, less involved portion of the caput. FIG. 17. Serial angiograms of a case with necrosis and unhealed fracture. Normal extension of the posterior collum branch (arrows) in inward rotation of the leg (*left*). The circulation became arrested when the leg was rotated outwardly (*right*, arrow).

## DISCUSSION

The vascular supply of the head of the femur has been the subject of earlier angiographic investigations in living persons with healthy hips (19, 10, 8) as well as with neck fractures (23, 19, 10, 8, 9, 17) and femoral head necrosis (19, 16, 10). In these investigations contrast material was usually injected through a long sharp needle into the common femoral artery in a retrograde direction, a convenient method for arteriography of the whole leg used for several decades. Mussbichler (19) used exclusively the blunt Seldinger cannula 20S in order to reduce the risk of arterial wall damage by the sharp tip of the needle. In the present study cannulas have been replaced by catheters, the use of which allows free rotational movements of the hip joint during arteriography. In this way angiograms could be obtained in different projections, which is desirable for accurate and reliable identification of the vessels and for studying the influence of different positions of the leg on arterial circulation. With this procedure a close relationship between malrotation of fractures and arrested circulation in the posterior collum branch could be proved.

Earlier angiographic methods were additionally improved in the present investigation by using serial exposures with an automatic filmchanger, permitting better registration of the arteries than was the case with only 3—4 exposures. By injection of contrast material through the loop-formed, red Odman-Ledin catheter, the vascular filling can be restricted to the external iliac artery and its branches which are responsible for the nutrition of the femoral head. For this reason this method was called "semiselective". The main advantage of this method was the avoidance of filling of the internal iliac artery, the branches of which are usually superimposed on the femoral head vessels. Application of the subtraction method, well established in other fields of angiography, is of great value for

FIG. 17. Serial angiograms of a case with necrosis and unhealed fracture. Normal extension of the posterior collum branch (arrows) in inward rotation of the leg (*left*). The circulation became arrested when the leg was rotated outwardly (*right*, arrow).

## DISCUSSION

The vascular supply of the head of the femur has been the subject of earlier angiographic investigations in living persons with healthy hips (19, 10, 8) as well as with neck fractures (23, 19, 10, 8, 9, 17) and femoral head necrosis (19, 16, 10). In these investigations contrast material was usually injected through a long sharp needle into the common femoral artery in a retrograde direction, a convenient method for arteriography of the whole leg used for several decades. Mussbichler (19) used exclusively the blunt Seldinger cannula 205 in order to reduce the risk of arterial wall damage by the sharp tip of the needle. In the present study cannulas have been replaced by catheters, the use of which allows free rotational movements of the hip joint during arteriography. In this way angiograms could be obtained in different projections, which is desirable for accurate and reliable identification of the vessels and for studying the influence of different positions of the leg on arterial circulation. With this procedure a close relationship between malrotation of fractures and arrested circulation in the posterior collum branch could be proved.

Earlier angiographic methods were additionally improved in the present investigation by using serial exposures with an automatic filmchanger, permitting better registration of the arteries than was the case with only 3—4 exposures. By injection of contrast material through the loop-formed, red Ödman-Ledin catheter, the vascular filling can be restricted to the external iliac artery and its branches which are responsible for the nutrition of the femoral head. For this reason this method was called "semiselective". The main advantage of this method was the avoidance of filling of the internal iliac artery, the branches of which are usually superimposed on the femoral head vessels. Application of the subtraction method, well established in other fields of angiography, is of great value for

reliable identification of small vessels and, not least, for the recognition of hypervascular areas such as were found in cases with femoral head necrosis.

In previous examinations of healthy hips, the vascular pattern, known from anatomical studies in cadavers and specimens, was to some extent identified angiographically. The examinations of Müssbichler (19) and Brugger (8) revealed in addition that the femoral head vessels could not be demonstrated in all cases examined. These observations are confirmed by the results of the present study, which further disclosed hypoplasia, ectopia, and non-filling of the posterior collum branch. In the last case the posterior collum branch was definitely not derived from the medial circumflex artery. As the latter as well as its inferior branch were well- and consistently filled with contrast medium, non-filling of the posterior collum branch cannot be due to technical errors. This is supported by the fact that this finding was frequently present bilaterally. Non-filling of the posterior collum branch is probably due to an undetectable ectopic origin or replacement of the branch by other sources of blood supply.

The absence of filling of the small femoral head vessels, noted in many cases, may be due to a too low concentration of contrast material and not least, to the smallness of their diameters (0.3 mm is generally accepted as the lower limit of angiographic registration of vessels). These factors should be considered when filling of the femoral head vessels is not obtained.

Selective internal iliac arteriography disclosed only small collaterals to the posterior collum branch in single cases. Filling of the internal iliac artery seems, therefore, of no practical use in angiographic examination of the hip except to demonstrate the acetabular artery and an ectopic origin of the posterior collum branch.

Previous angiographic examinations of femoral neck fractures have mainly been made in an attempt to predict the fate of the femoral head as regards development of necrosis. Rook (23) concluded that "inadequate" or "poor" filling of the femoral, deep femoral, and circumflex arteries indicates reduced blood supply to the femoral head, and predicted a poor prognosis in such cases. The value of this observation, however, has not been checked by follow-up studies. Local disturbances of the circulation in patients with fresh medial neck fractures was demonstrated for the first time by Muss-

bichler (19), and later confirmed by the findings of Hipp (10), Bruger (8), and Maurer et al. (17). No differentiation between circulatory disturbances and anomalies, such as hypoplasia or non-filling of the posterior collum branch, or individual variations in the filling of the femoral head vessels has been made in the studies of these authors. It is obvious, however, that a clear differentiation between a circulatory lesion and normal, individual variations, including anomalies, is of the utmost importance for preventing misinterpretation of the findings.

*The diagnosis of arrested circulation* should be based on a visible interruption of the flow of contrast material, which usually pools in the intact trunk of the vessel. In the case of anomalous origin, no part of the vessel will be filled (Fig. 13) and in the case of hypoplasia, the vessel is narrow and short but otherwise normal. Atherosclerotic changes can also give rise to misinterpretation. They are not an uncommon finding either in affected or unaffected hips and are characterized by irregularities of the lumen caused by plaques attached to the arterial wall.

Trueta and Harrison (29) suggested from their anatomical studies that the superior retinacular artery is exposed to damage along the neck by varus fractures, whereas valgus fractures do not involve this artery which is the vessel most responsible for nutrition of the femoral head. This should explain the high frequency of femoral head necrosis after varus fractures. Backman (3, 4) contributed to this subject by experimental fractures in specimens of human hips as well as by follow-up studies of patients with neck fractures. He could demonstrate that malrotation of the fracture is responsible for extensive rupture of the superior retinaculum, where the superior retinacular artery runs, as well as for the development of femoral head necrosis. The deleterious role of malrotation upon the circulation to the femoral head could be definitely proved in the present study by angiography of malrotated fractures before and after reduction. It seems most likely that the immediate cause of the circulatory arrest is due to kinking or tearing of the posterior collum branch because of the malrotation of the fracture fragments. This assumption is supported by the successful provocation of circulatory arrest in old, unhealed fractures by outward rotation of the leg.

The superior retinacular artery may also be primarily affected, regardless of whether the circulation in the posterior collum branch

is arrested or not. Interruption of the superior retinacular artery has been demonstrated micro-angiographically after neck fracture in specimens of human hips (26). However, angiographic demonstration of lesions confined to the superior retinacular artery or the other femoral head vessels is not possible *in vivo* because of the high frequency of individual variation demonstrated by the present study of normal hips.

Prospective studies of angiographically examined neck fractures have been carried out by Brünner et al. (9). Their results agree with those of the present study, showing a close relationship between the circulatory condition in the posterior collum branch and the occurrence of necrosis. Isolated cases, however, deviated, thus indicating that additional factors may influence the fate of the femoral head: The most important being the *duration* of circulatory arrest. Its protraction is generally leading to arterial thrombosis with irreversible blockage. A similar process may, in the case of neck fractures, involve the superior retinacular artery e.g. the termination of the posterior collum branch.

From experiments on rabbits it is known that the osteoblasts of the femoral head may tolerate an interruption of the blood supply for up to 6 hours (34, 24). Postponed reduction of the fracture-dislocation maintaining circulatory arrest, may thus be responsible for the development of femoral head necrosis, whereas "early" reduction, advocated by several authors (5, 18, 27, 28), may protect or restore normal circulation and avoid the development of necrosis. Optimal effect in preventing necrosis of the femoral head may be expected from fracture reduction performed as an emergency as has been proposed by Strange (28). Forced inward rotation and fixation of the malrotated leg carried out as an emergency could be an important link in the treatment of malrotated fractures.

Survival of the femoral head may also be helped by pre-existent collateral circulation within the caput, demonstrated microangiographically by Sewitt and Thompson (25) or by extraosseous communications between the trochanteric vessels and the superior retinacular artery (14) and/or between the inferior gluteal artery and the peripheral part of the posterior collum branch — shown in the present study of healthy hips. As one or several of these communications may exist, a reliable prognosis based on the circulatory

condition in the posterior collum branch alone cannot be made in each individual case.

While non-filling of the superior retinacular artery in individual cases is inconclusive, its filling, obtained in 7 fracture cases, seems to indicate viability of the femoral head, as no necrosis of the head was present at follow-up in any of these 7 cases. However, the prognostic value of this observation needs to be proved in a larger material and over a longer period before definite statements can be made.

The mechanism of circulatory arrest in pertrochanteric fractures, in which necrosis usually does not occur, may be different from that in neck fractures. The location of the pertrochanteric fracture, far distal and lateral to the posterior collum branch and particularly to the superior retinacular artery, makes it likely that the circulatory disturbance is actually less severe and therefore of a more transient character than in the case of neck fractures.

Delayed circulation in the posterior collum branch without circulatory arrest is thought to indicate impairment of emptying of this artery due to damage to its peripheral part or its main branch, the superior retinacular artery. Delayed circulation was found in 3 cases out of 27 with fresh fractures and in 13 out of 21 with established necrosis. In the latter condition, delayed circulation occurred not only more frequently but was also more pronounced than in recent fractures. This indicates that the degree of the circulatory disturbance progresses simultaneously with the development of necrosis. The consistent absence of filling of the superior retinacular artery throughout the whole necrosis material further emphasizes the nature of the nutritional disorder of the femoral head. Hypertrophy and/or increased filling frequency of the other femoral head vessels as well as the incidence of hypervascular areas point to the occurrence of a re-vascularization process at the fracture site and at the periphery of the necrotic head similar to that demonstrated histologically in humans subjects and experiment animals (26, 22).

is arrested or not. Interruption of the superior retinacular artery has been demonstrated micro-angiographically after neck fracture in specimens of human hips (26). However, angiographic demonstration of lesions confined to the superior retinacular artery or the other femoral head vessels is not possible *in vivo* because of the high frequency of individual variation demonstrated by the present study of normal hips.

Prospective studies of angiographically examined neck fractures have been carried out by Brünner et al. (9). Their results agree with those of the present study, showing a close relationship between the circulatory condition in the posterior collum branch and the occurrence of necrosis. Isolated cases, however, deviated, thus indicating that additional factors may influence the fate of the femoral head: The most important being the *duration* of circulatory arrest. Its protraction is generally leading to arterial thrombosis with irreversible blockage. A similar process may, in the case of neck fractures, involve the superior retinacular artery e.g. the termination of the posterior collum branch.

From experiments on rabbits it is known that the osteoblasts of the femoral head may tolerate an interruption of the blood supply for up to 6 hours (34, 24). Postponed reduction of the fracture-dislocation maintaining circulatory arrest, may thus be responsible for the development of femoral head necrosis, whereas "early" reduction, advocated by several authors (5, 18, 27, 28), may protect or restore normal circulation and avoid the development of necrosis. Optimal effect in preventing necrosis of the femoral head may be expected from fracture reduction performed as an emergency as has been proposed by Strange (28). Forced inward rotation and fixation of the malrotated leg carried out as an emergency could be an important link in the treatment of malrotated fractures.

Survival of the femoral head may also be helped by pre-existent collateral circulation within the caput, demonstrated microangiographically by Sewitt and Thompson (25) or by extraosseous communications between the trochanteric vessels and the superior retinacular artery (14) and/or between the inferior gluteal artery and the peripheral part of the posterior collum branch — shown in the present study of healthy hips. As one or several of these communications may exist, a reliable prognosis based on the circulatory

D. Other improvements comprised the use of an automatic film-changer taking 15 exposures over 15 seconds and application of the subtraction method.

The use of blunt Seldinger cannulas and catheters in particular as opposed to the sharp needles used by other authors diminishes the risk of arterial wall lesions. Catheters are to be preferred as they allow studies in different positions of the hip joint, which is desirable for reliable identification of vessels and of conditions of circulatory disturbance. Semiselective angiography with the red Odman-Ledin catheter showed optimal results as regards identification of the femoral head vessels. The use of serial angiography and the application of the subtraction method further improved the registration of the arterial circulation and identification of vessels.

*ad 2* Ninety-two healthy hips were examined angiographically. The findings revealed a great individual variation of the vascular pattern. This concerned particularly the posterior collum branch which was hypoplastic in 3 cases and of anomalous origin in 11. Demonstration of the superior retinacular artery in the total material of healthy hips was successful in about 69 % of the cases, of the inferior retinacular artery in 63 %, and of the acetabular artery in 40 % with general arteriography and in 27 % with the semiselective method. The incidence of filling of the other femoral head vessels was not influenced by the arteriographic method used. The existence of small anastomoses between the inferior gluteal artery and the peripheral part of the posterior collum branch was demonstrated by internal iliac arteriography in 3 out of 14 cases. Filling of the internal iliac artery also made possible confirmation of an ectopic origin of the posterior collum branch in the inferior gluteal artery in 2 cases.

Ignorance of these angiographic findings in healthy hips must necessarily give rise to misinterpretation of angiograms in fractures, necroses or other affections of the hip.

*ad 3* A total of 49 cases, 37 with medial neck and 12 with peritrochanteric fractures, were examined. In 37 of them angiography was carried out before nailing (Paragraphs A—C below), 37 were examined after the operation (D), and in 27 cases with medial neck

## GENERAL SUMMARY AND CONCLUDING REMARKS

The present angiographic investigation was concerned with the arterial supply of the hip in living persons. It comprised studies of (1) arteriographic methods, (2) the vascular anatomy of healthy hips, (3) the vascular anatomy of neck and pertrochanteric fractures, and (4) necrosis of the femoral head after neck fracture. The main results and conclusions of the investigation are summarized as follows:

*ad 1.* In the demonstration of the arteries of the hip, the following methods were applied:

- A. A blunt Seldinger cannula was used in 34 cases in which 20 ml Dijodon 50 % was injected retrogradely into the common femoral artery. In 99 cases, 16 ml Urografin 76 % was injected through a polyethylene catheter into the common femoral or external iliac artery. These types of injection were termed "general arteriography" since, usually, both the external and internal iliac arteries filled.
- B. A new catheter technique for semiselective visualization of the arteries of the hips was devised. It consisted of antegrade, peripheral injection of 10 ml Urografin 76 % either through a distally inserted polyethylene catheter (3 cases) or a loop-formed, red Odman-Ledin catheter (26 cases). The purpose of this type of examination, only used in the normal material, was to avoid retrograde filling of the branches of the internal iliac artery superimposed on the vessels of the femoral head.
- C. Selective internal iliac arteriography was carried out in 14 cases in order to study the contribution of this artery to the supply of the hip.

D. Other improvements comprised the use of an automatic film-changer taking 15 exposures over 15 seconds and application of the subtraction method.

The use of blunt Seldinger cannulas and catheters in particular as opposed to the sharp needles used by other authors diminishes the risk of arterial wall lesions. Catheters are to be preferred as they allow studies in different positions of the hip joint, which is desirable for reliable identification of vessels and of conditions of circulatory disturbance. Semiselective angiography with the red Ödman-Ledin catheter showed optimal results as regards identification of the femoral head vessels. The use of serial angiography and the application of the subtraction method further improved the registration of the arterial circulation and identification of vessels.

ad 2 Ninety-two healthy hips were examined angiographically. The findings revealed a great individual variation of the vascular pattern. This concerned particularly the posterior collum branch which was hypoplastic in 3 cases and of anomalous origin in 11. Demonstration of the superior retinacular artery in the total material of healthy hips was successful in about 69 % of the cases, of the inferior retinacular artery in 63 %, and of the acetabular artery in 40 % with general arteriography and in 27 % with the semiselective method. The incidence of filling of the other femoral head vessels was not influenced by the arteriographic method used. The existence of small anastomoses between the inferior gluteal artery and the peripheral part of the posterior collum branch was demonstrated by internal iliac arteriography in 3 out of 14 cases. Filling of the internal iliac artery also made possible confirmation of an ectopic origin of the posterior collum branch in the inferior gluteal artery in 2 cases.

Ignorance of these angiographic findings in healthy hips must necessarily give rise to misinterpretation of angiograms in fractures, necroses or other affections of the hip.

ad 3 A total of 49 cases, 37 with medial neck and 12 with per-trochanteric fractures, were examined. In 37 of them angiography was carried out before nailing (Paragraphs A—C below), 37 were examined after the operation (D), and in 27 cases with medial neck

## GENERAL SUMMARY AND CONCLUDING REMARKS

The present angiographic investigation was concerned with the arterial supply of the hip in living persons. It comprised studies of (1) arteriographic methods, (2) the vascular anatomy of healthy hips, (3) the vascular anatomy of neck and pertrochanteric fractures, and (4) necrosis of the femoral head after neck fracture. The main results and conclusions of the investigation are summarized as follows:

*ad 1.* In the demonstration of the arteries of the hip, the following methods were applied:

- A. A blunt Seldinger cannula was used in 34 cases in which 20 ml Dijodon 50 % was injected retrogradely into the common femoral artery. In 99 cases, 16 ml Urografin 76 % was injected through a polyethylene catheter into the common femoral or external iliac artery. These types of injection were termed "general arteriography" since, usually, both the external and internal iliac arteries filled.
- B. A new catheter technique for semiselective visualization of the arteries of the hips was devised. It consisted of antegrade, peripheral injection of 10 ml Urografin 76 % either through a distally inserted polyethylene catheter (3 cases) or a loop-formed, red Ödman-Ledin catheter (26 cases). The purpose of this type of examination, only used in the normal material, was to avoid retrograde filling of the branches of the internal iliac artery superimposed on the vessels of the femoral head.
- C. Selective internal iliac arteriography was carried out in 14 cases in order to study the contribution of this artery to the supply of the hip.

It is suggested that filling of the superior retinacular artery may indicate maintained circulation to the femoral head. However, its non-filling should in the individual case, not be interpreted as a circulatory lesion. It seems likely that the existence of an efficient collateral circulation, angiographically not demonstrable, may keep the caput alive in individual cases even though the circulation in the posterior collum branch or superior retinacular artery has been or still is arrested. This would explain the avoidance of caput necrosis seen in 2 cases with arrested circulation in the fresh fractures.

*Reduction of the malrotation leading to restoration of the circulation in the posterior collum branch, suggests that this procedure should be carried out as an emergency in order to shorten the period of circulatory arrest. This may be a valuable link in the treatment of malrotated neck fractures.*

*ad 4* Twenty-one cases of femoral head necrosis after medial neck fracture were examined and associated with the following angiographic findings:

- A The posterior collum branch showed delayed circulation in 13 cases.
- B The superior retinacular artery was not filled in any case.
- C. The acetabular and ligamentum teres arteries showed an increased frequency of filling and the inferior retinacular and acetabular arteries were enlarged, compared with the findings from the contralateral, healthy hip. Moreover, hypervascular areas at the fracture site and the medial, less-involved part of the caput were observed.

The arteriographic findings confirm the general opinion of avascularity of the necrotic femoral head but also show the occurrence of peripheral revascularization

fractures follow-up studies were made (E—H). The findings are listed below (A—G concern the circulation in the posterior collum branch).

- A. In recent fractures the circulation in the posterior collum branch was normal in 19 cases and disturbed in 18. The latter condition comprised delayed circulation, 3 cases, and arrested circulation, 15 cases.
- B. Circulatory disturbance was exclusively present in fractures which were in varus and dorsal angulation or in dorsal angulation of at least 40°.
- C. Arrested circulation was restored to "normal" or "delayed" after reduction of the fracture during the angiographic examination. This was shown in 5 out of 12 cases.
- D. After operative reduction and nailing, arrested circulation was not noted in any of the 37 cases examined. However, in 3 neck and 1 pertrochanteric fracture, the circulation remained delayed.
- E. Follow-up studies could be performed in a total of 27 neck fractures, 18 of them angiographically examined before fracture reduction and 24 after operative reduction.
- F. Femoral head necrosis developed in 7 out of 9 cases of fresh medial neck fractures in which the circulation was arrested before reduction, whereas necrosis was noted in only 1 out of 9 neck fractures with normal or delayed circulation. The probability of committing wrong decisions, according to the sign-test, rejecting the null hypothesis,  $P(\text{necrosis}) = 0.5$ , is less than 9 % and 2 % respectively.
- G. Out of the 24 cases with neck fractures angiographically examined after operation, the circulation was normal in 21 cases and delayed in the remaining 3. At follow-up, necrosis had occurred in 9 cases, in 2 of which the circulation had been delayed and in 7 of which it had been normal.
- H. The superior retinacular artery filled in none of the 11 neck fractures which later developed necrosis. It was, however, filled in 7 out of the 16 cases in which necrosis was not established at follow-up.

It is suggested that filling of the superior retinacular artery may indicate maintained circulation to the femoral head. However, its non-filling should in the individual case, not be interpreted as a circulatory lesion. It seems likely that the existence of an efficient collateral circulation, angiographically not demonstrable, may keep the caput alive in individual cases even though the circulation in the posterior collum branch or superior retinacular artery has been or still is arrested. This would explain the avoidance of caput necrosis seen in 2 cases with arrested circulation in the fresh fractures.

Reduction of the malrotation leading to restoration of the circulation in the posterior collum branch, suggests that this procedure should be carried out as an emergency in order to shorten the period of circulatory arrest. This may be a valuable link in the treatment of malrotated neck fractures.

ad 4 Twenty-one cases of femoral head necrosis after medial neck fracture were examined and associated with the following angiographic findings:

- A. The posterior collum branch showed delayed circulation in 13 cases.
- B. The superior retinacular artery was not filled in any case.
- C. The acetabular and ligamentum teres arteries showed an increased frequency of filling and the inferior retinacular and acetabular arteries were enlarged, compared with the findings from the contralateral, healthy hip. Moreover, hypervascular areas at the fracture site and the medial, less-involved part of the caput were observed.

The arteriographic findings confirm the general opinion of avascularity of the necrotic femoral head but also show the occurrence of peripheral revascularization.

## ACKNOWLEDGEMENTS

To the Head of Roentgen Department I, Professor Georg-Fredrik Saltzman, M. D., I wish to express my deepest gratitude for promoting my work, as well as for encouragement and constructive criticism.

It is a pleasure to express my thanks to my chief, Docent Bengt Liliequist, M. D., Head of Roentgen Department II, for giving me the opportunity to perform this work and for his valuable support.

I am also deeply indebted to Professor John Sevastikoglou, M. D., Head of the Orthopaedic Department, as well as to his associates, Docent Carl Arnoldi, M. D., and Docent Rudolf Lemperg, M. D., who have followed the progress of the investigation with great interest, have provided clinical material for my studies, and have given many valuable suggestions in inspiring discussions.

I wish to express my sincere thanks to Professor Stig Borgström, M. D., Head of the Surgical Department, and his staff for their support during my studies.

Technical advice given by Dr. Paul Junghagen is gratefully acknowledged.

I am also indebted to Docent Bertil Nordlund, M. D., for critical reading of the manuscript and encouraging talks.

This investigation was supported by grants from the Faculty of Medicine of the University of Umeå and Schering AG.

Umeå, April 1970.

## ACKNOWLEDGEMENTS

The subject of this study was originally suggested by Professor A. Langenskiöld, M.D., who, during the subsequent years 1964—1970, provided continuous counsel and encouragement to this research project, beginning with the first animal experiments and ending with the final questions relating to its publication. For this and for the positive effect the atmosphere in the hospital has had on my work, I wish to express my sincere thanks

I am also deeply grateful to Professor E. Saxén, M.D., Head of the III Department of Pathology, University of Helsinki, for his constructive criticism during the course of my work

In addition, I am greatly indebted to Docent T. Rytömaa, M. D., for stimulating discussions and suggestions.

I am very grateful to Dr. Clyde L. Nash Jr, M.D., Cleveland, Ohio, for his critical reading of the manuscript.

My thanks are due to K. Koskenniemi, M.Sc., for the statistical treatment of the results at the Computing Centre of the University of Helsinki. I am also grateful to Mrs Tuulikki Juusela, M.Sc. (Pol.), for her assistance in the compilation of the tables.

I wish to thank Mrs Eila Pohjola and Miss Ritva Sohlman for their help with the animal experiments, in making histological sections and autoradiographs and in drawing the graphs. Miss Lempi Mikkola took all the photographs for the present study and I thank her for her contribution. I also wish to thank all the other persons I have imposed upon in the course of my work.

With a slightly bad conscience but a truly warm heart, I want to thank my family for their self-denial and patience.

As a member of Professor A. Langenskiöld's research team, I have received support from the Sigrid Juselius Foundation and the Scientific Fund of the Invalid Foundation.

Helsinki, April 1970

## INTRODUCTION

During normal longitudinal growth in the metaphysis of a tubular bone, tendinous and ligamentous insertions maintain their positions relative to the increasing size of the bone. This means that the displacement of the site of insertion in regard to the central part of the diaphysis does not depend directly on the longitudinal growth of the metaphysis between the insertion site and the epiphyseal plate (Figs. 1 A and B)

The mechanism of the displacement of the sites of these insertions is the subject of the present study. Displacement is seen most distinctly in such diaphyseal insertions where a clearly demarcated bundles of collagenous fibres penetrate the bone. When a tendon or ligament only inserts itself into the periosteum, this displacement is associated with the relation between the growth mechanism of the periosteum and diaphysis (Warwick & Wiles 1934), but this problem is outside the scope of the present study.

The name Sharpey's fibres is often used in studies of the structure of the insertion areas. According to the current definition, Sharpey's fibres anchor tendons and ligaments to bone (Ham 1965). Schneider (1956) defines the term differently: Sharpey's fibres do not attach tendons to bones, but fix only the periosteum to the bone, while «tendon fibres» (Sehnenfaser) anchor the tendons and ligaments to the bone. The formation of bone at the site of insertion was termed «tendinous osteogenesis» (tendinöse Osteogenese) by Biermann (1957) to emphasize that tendinous tissue does not simply calcify, but that tendinous bone is being formed by gradual differentiation.

The displacement of epiphyseal insertion in relation to the diaphysis is a direct consequence of the longitudinal growth in the epiphyseal plate and is therefore not dealt with in the present work. Slight displacement of these insertions in relation to the epiphyseal nucleus takes place and the collagenous fibres remain in the bone during growth (Schneider 1956)

displacement of the tendon insertions in relation to the central part of the diaphysis during growth (Figs. 1 A and B) has not previously been studied. The growth of the insertion areas can be studied in relation to cells, bone matrix, connective tissue surrounding the tendon and growth disturbances.

$^{35}\text{S}$ -sulphate is a suitable medium for autoradiographic studies of the formation of the ground substance of tendons, ligaments, bone matrix and cartilage tissue i.e., all possible tissues at the site of insertion. The exact chemical composition of the radioactive compound in the insertion areas is not known in detail, but the stages of incorporation of  $^{35}\text{S}$ -sulphate in the organism are relatively well-known (sulphated glycosamino glycans) Dzwiatkowski 1951, Jackson 1953, Engfeldt & Westerborn 1960, Mancini et al. 1961, Brondolo & Randelli 1962, Crane 1962). In practice,  $^{35}\text{S}$ -sulphate can be used to label only the organic matrix of bone, whereas oxytetracycline can be used to label the mineral component of bone (Ibsen & Urist 1962). When this antibiotic is administered to growing animals, it is deposited in bone in connection with the ossification process (Milch et al. 1957). Because tetracyclines give a yellow fluorescence in ultraviolet light (Saltzman 1950), they can be used as bone label.

Another technique for studying the mechanism of growth of tendon and ligament insertions is by disruption of normal growth. Fixation of a metal wire in the metaphysis between the insertion area of a tendon (or ligament) and the epiphyseal plate, inhibits the normal displacement of the site of insertion.

Still another technique of study is based on the fact that cells in the premitotic S-phase incorporate  $^3\text{H}$ -thymidine and that the labelled daughter cells can then be identified autoradiographically even after several subsequent mitoses.

## MATERIAL AND METHODS

Four different methods (see below 1—4) were used for the studies of the growth mechanism at the site of insertion of tendons and ligaments.

1)  $^{35}\text{S}$ -sulphate. A total of 47 rabbits aged from 9—210 days at the time of administration of the labelled substance were used for the autoradiographic studies.  $^{35}\text{S}$ -sulphate was given in a single intraperitoneal injection, 1—5  $\mu\text{Ci}$  per gram of body weight to each animal. The rabbits were killed 1.2 hours—60 days after the injection. The

1 A

1 B

**Fig. 1 A:** Contour drawings of the rabbit's tibia during two different stages of growth. The tibia grows 57 per cent from the proximal epiphyseal plate and 43 per cent from the distal plate. The shape of the tibia at the younger stage is denoted by the broken line. The contour drawn in full shows a later stage when the length of the tibia had increased by 70 per cent compared to the younger stage. The displacement of the site of insertion of the medial collateral ligament during the period of growth from the first stage to the second is denoted by *a*.

**Fig. 1 B:** Contour drawings of the femur of a rabbit at two stages of growth. The shape of the femur at the initial observation is denoted by the broken line. *a* denotes the distance which the insertion site of the tendon of the pectineus muscle is displaced in relation to the central part of the diaphysis during growth of the bone from the size at initial observation until the size shown by the fully drawn contour. Note that 30 per cent of the longitudinal growth of the femoral diaphysis takes place at the proximal metaphysis.

The results mentioned above were obtained chiefly by histological studies, and there thus seemed reason to check them by autoradiographic studies. These studies with  $^{35}\text{S}$ -sulphate have established that substances of the periosteum are retained in the bone during the growth process (Amprino 1955). However, the actual mechanism of the

displacement of the tendon insertions in relation to the central part of the diaphysis during growth (Figs 1 A and B) has not previously been studied. The growth of the insertion areas can be studied in relation to cells, bone matrix, connective tissue surrounding the tendon and growth disturbances.

$^{35}\text{S}$ -sulphate is a suitable medium for autoradiographic studies of the formation of the ground substance of tendons, ligaments, bone matrix and cartilage tissue i.e., all possible tissues at the site of insertion. The exact chemical composition of the radioactive compound in the insertion areas is not known in detail, but the stages of incorporation of  $^{35}\text{S}$ -sulphate in the organism are relatively well-known (sulphated glycosamino glycans) *Dziewiatkowski 1951, Jackson 1953, Engfeldt & Westerborn 1960, Mancini et al. 1961, Brondolo & Randelli 1962, Crane 1962*) In practice,  $^{35}\text{S}$ -sulphate can be used to label only the organic matrix of bone, whereas oxytetracycline can be used to label the mineral component of bone (*Ibsen & Urist 1962*) When this antibiotic is administered to growing animals, it is deposited in bone in connection with the ossification process (*Nilch et al 1957*). Because tetracyclines give a yellow fluorescence in ultraviolet light (*Saltzman 1950*), they can be used as bone label

Another technique for studying the mechanism of growth of tendon and ligament insertions is by disruption of normal growth. ## MATERIAL AND METHODS

Four different methods (see below 1—4) were used for the studies of the growth mechanism at the site of insertion of tendons and ligaments.

1)  $^{35}\text{S}$ -sulphate: A total of 47 rabbits aged from 9—210 days at the time of administration of the labelled substance were used for the autoradiographic studies  $^{35}\text{S}$ -sulphate was given in a single intraperitoneal injection, 1—5  $\mu\text{Ci}$  per gram of body weight to each animal. The rabbits were killed 12 hours—60 days after the injection. The

symbol »T« in the text and in the figures refers to this time. The insertion of three tendons (the pectineus and the pectoralis major muscles and the patellar ligament) and two ligaments (the crural ligament, which corresponds to the extensor retinaculum in man, and the medial collateral ligament of the knee) were studied. Immediately after the animals were killed, the bones and tendons to be examined were dissected as a unit. These specimens were studied using routine histological and autoradiographic techniques similar to those adopted by Langenskiöld et al. (1967). A total of 755 autoradiographs were made from the histological sections.

2) *Oxytetracycline* (Terramycin®, Pfizer) studies were also performed, giving a single injection, 50 mg/kg of body weight, to 15 rabbits aged from 14–28 days. The rabbits were killed within 4–26 days of administration of the antibiotic. The techniques for examination of the bones and for photography were those used by Puranen (1966) and Karaharju (1967).

3) In the experiments with implantation of metal markers, 60 rabbits were used whose ages ranged from 11–40 days at the time of operation. Twenty-nine rabbits into which no metal markers were fixed served as the control group. Indian ink marks were used in the ligaments of some animals instead of or in addition to the metal markers. For both the metal markers and the Indian ink marks, the method employed was essentially that used by Crawford (1950 and 1954).

Metal markers were used in order to follow the changes by radiography. The animals were killed 11–221 days after the operation. The tendons and ligaments were carefully dissected and the location of the metal markers was verified. The overall length of the bones (from proximal epiphyseal plate to distal epiphyseal plate =  $l_1$ ) and the distance of the metal markers from one another and from the epiphyseal plate were measured from the radiographs. The measurements of 21 rabbits were treated mathematically and statistically by a digital computer (IBM 1620) at the Computing Centre of the University of Helsinki. Growth curves and specific growth rates were determined mathematically from measurements obtained from the radiographs. The statistical means of these parameters were computed.

After fixation in 10 per cent neutral formalin and decalcification in five per cent nitric acid, the specimens were embedded in paraffin wax, sectioned at 10  $\mu$  and stained with Weigert's haematoxylin van Gieson.

4) Twenty-two rabbits whose ages ranged from 7—18 days at the time of administration of the radioisotope were used for the experiments with  $^3\text{H}$ -thymidine. Each animal received 1.3—4  $\mu\text{Ci}$  per gram of body weight of  $^3\text{H}$ -thymidine in a single intraperitoneal injection. The animals were killed at intervals of two hours to five days after the thymidine administration. The bone and tendon were dissected as a unit immediately after killing and the tissues were fixed in 10 per cent neutral formalin and decalcified 5—15 days in a 32 per cent solution of EDTA. The specimens were embedded in paraffin wax, sectioned at five  $\mu$  and cleared in xylol. Autoradiographs were prepared by the stripping film technique (Kodak AR 10). After exposure times of 1—3 months, the films were processed in Kodak D 19b developer and acid fixer and the cells were stained with methylene blue. The insertion areas were photomicrographed (magnification  $\times 100$ ) from these sections and the labelling of every nucleus seen in the photograph was surveyed at  $\times 1000$  magnification under a microscope. All labelled nuclei were marked with Indian ink in the photograph because from the photograph at this magnification alone it was not possible to distinguish reliably a non-labelled nucleus from a faintly labelled nucleus. The longitudinal section of the insertion region of the tendon of the pectineus muscle was divided into five areas as shown in Fig 6. For each area, the labelling index ( $p$ ) was determined from the formula:

$$p = \frac{s_i}{a_i \cdot n_i}, \text{ where}$$

$s_i$  - number of autoradiographically positive cells in area  $i$ ,  
 $a_i$  - size of area  $i$  (measured by planimeter from the photograph),  
 $n_i$  - total cells counted in area  $i$  (for the determination, the microscopic image was superimposed with 25 points arranged as in the Zeiss Integrating Eye-Piece 1)

## RESULTS

1) *Incorporation of  $^{35}\text{S}$ -sulphate:* Fig 2 summarizes the results obtained from the  $^{35}\text{S}$ -sulphate autoradiographs of the pectineus tendon insertion area. Two hours after administration of the labelled sulphate, the radioactivity is strongest in the insertion, periosteum, tendon and bone marrow which has not been marked at all in Fig 2. At the site of insertion the radioactivity does not extend to the bone and there are no distinct differences in labelling intensity among the different areas

symbol »T« in the text and in the figures refers to this time. The insertion of three tendons (the pectineus and the pectoralis major muscles and the patellar ligament) and two ligaments (the crural ligament, which corresponds to the extensor retinaculum in man, and the medial collateral ligament of the knee) were studied. Immediately after the animals were killed, the bones and tendons to be examined were dissected as a unit. These specimens were studied using routine histological and autoradiographic techniques similar to those adopted by Langenskiöld et al. (1967). A total of 755 autoradiographs were made from the histological sections.

2) *Oxytetracycline* (Terramycin®, Pfizer) studies were also performed, giving a single injection, 50 mg/kg of body weight, to 15 rabbits aged from 14—28 days. The rabbits were killed within 4—26 days of administration of the antibiotic. The techniques for examination of the bones and for photography were those used by Puranen (1966) and Karaharju (1967).

3) In the experiments with implantation of metal markers, 60 rabbits were used whose ages ranged from 11—40 days at the time of operation. Twenty-nine rabbits into which no metal markers were fixed served as the control group. Indian ink marks were used in the ligaments of some animals instead of or in addition to the metal markers. For both the metal markers and the Indian ink marks, the method employed was essentially that used by Crawford (1950 and 1954).

Metal markers were used in order to follow the changes by radiography. The animals were killed 11—221 days after the operation. The tendons and ligaments were carefully dissected and the location of the metal markers was verified. The overall length of the bones (from proximal epiphyseal plate to distal epiphyseal plate =  $l_0$ ) and the distance of the metal markers from one another and from the epiphyseal plate were measured from the radiographs. The measurements of 21 rabbits were treated mathematically and statistically by a digital computer (IBM 1620) at the Computing Centre of the University of Helsinki. Growth curves and specific growth rates were determined mathematically from measurements obtained from the radiographs. The statistical means of these parameters were computed.

After fixation in 10 per cent neutral formalin and decalcification in five per cent nitric acid, the specimens were embedded in paraffin wax, sectioned at 10  $\mu$  and stained with Weigert's haematoxylin van Gieson.

4) Twenty-two rabbits whose ages ranged from 7—18 days at the time of administration of the radioisotope were used for the experiments with  $^3\text{H}$ -thymidine. Each animal received 13—4  $\mu\text{Ci}$  per gram of body weight of  $^3\text{H}$ -thymidine in a single intraperitoneal injection. The animals were killed at intervals of two hours to five days after the thymidine administration. The bone and tendon were dissected as a unit immediately after killing and the tissues were fixed in 10 per cent neutral formalin and decalcified 5—15 days in a 32 per cent solution of EDTA. The specimens were embedded in paraffin wax, sectioned at five  $\mu$  and cleared in xylol. Autoradiographs were prepared by the stripping film technique (Kodak AR 10). After exposure times of 1—3 months, the films were processed in Kodak D 19b developer and acid fixer and the cells were stained with methylene blue. The insertion areas were photomicrographed (magnification  $\times 100$ ) from these sections and the labelling of every nucleus seen in the photograph was surveyed at  $\times 1000$  magnification under a microscope. All labelled nuclei were marked with Indian ink in the photograph because from the photograph at this magnification alone it was not possible to distinguish reliably a non-labelled nucleus from a faintly labelled nucleus. The longitudinal section of the insertion region of the tendon of the pectineus muscle was divided into five areas as shown in Fig 6. For each area, the labelling index ( $p$ ) was determined from the formula:

$$p_i = \frac{s_i}{a_i \cdot n_i}, \text{ where}$$

$s_i$  = number of autoradiographically positive cells in area  $i$ ;

$a_i$  = size of area  $i$  (measured by planimeter from the photograph);

$n_i$  = total cells counted in area  $i$  (for the determination, the microscopic image was superimposed with 25 points arranged as in the Zeiss Intergrating Eye-Piece I)

## RESULTS

1) *Incorporation of  $^{35}\text{S}$ -sulphate* Fig. 2 summarizes the results obtained from the  $^{35}\text{S}$ -sulphate autoradiographs of the pectineus tendon insertion area. Two hours after administration of the labelled sulphate, the radioactivity is strongest in the insertion, periosteum, tendon and bone marrow which has not been marked at all in Fig. 2. At the site of insertion the radioactivity does not extend to the bone and there are no distinct differences in labelling intensity among the different areas

Fig. 2: Schematic summary of the results from autoradiographic studies. Outlines have been drawn for the proximal end of the femur and the tendon of the pectineus muscle with its insertion. Radioactivity is denoted in grey. Two days after the administration of the isotope the bone at the insertion region displays a very narrow radioactive area which remains in the bone. Twenty days after the injection, a radioactive zone is seen in the bone below the tendon-bone boundary of the insertion area. There is a very faintly radioactive area between this zone and the tendon-bone boundary. The exposure times were chosen to show the most radioactive areas as equally dark in all five phases (h = hours, other figures days)

of the region of insertion. However, two days after the administration of the radioisotope an essential change occurred in the localisation of the radioactivity and there was labelling in the bone adjacent to the tendon-bone boundary of the insertion area. Eight days after the administration of  $^{35}\text{S}$ -sulphate, a weakly radioactive area could be noted in the tendon-bone boundary. It was clearly distinguished from the more strongly radioactive tendon and bone. The change is obvious when this phase is compared with the preceding phase. Intensity of

Fig. 3: Diagram of tetracycline studies. The grey shading represents the yellow fluorescence of the distal insertion area of the pectineus muscle of rabbit femur. The animal was given oxytetracycline four days before it was killed (left). In the picture on the right, the rabbit was given antibiotics 25 days before it was killed, and there is non-fluorescing bone between the tendon-bone borderline and the fluorescing bone.

labelling in the photographs of the different phases of this study cannot be directly compared as the exposure times had to be varied in relation to the time from the administration of the labelled substance (cf. Langenskiöld et al 1967).

The changes in labelling pattern in the early stages became more pronounced and, by 13 days after the administration of the isotope, the labelling was most prominent in the bone bordering the tendon insertion. This radioactive zone was farther from the tendon-bone boundary than in the previous phase. The tendon-bone boundary and the bone close to this area were very weakly labelled. Radioactivity in the actual insertion and in the tendon was moderate. At later stages after the administration of  $^{35}\text{S}$ -sulphate, the strongly radioactive zone in bone was more distal from the tendon-bone boundary.

2) *Binding of oxytetracycline to the bone*: Fig. 3 is a drawing of longitudinal section made through the insertion of the tendon of the pectineus muscle. Four days after the administration of the antibiotic, fluorescing bone (the grey areas in Fig. 3 represent bone that fluoresces yellow in ultraviolet light) is seen on the distal side of the site of insertion in a narrow zone close to the tendon-bone boundary. Fluorescing bone is also seen subperiosteally on the proximal aspect of the insertion. Three weeks later, the fluorescing zone was still visible, but non-

Fig. 4: Contour drawings of the rabbit's tibia during two different stages of growth. At the stage seen on the right it is about 70 per cent larger than at the stage immediately postoperatively seen on the left. The growth of two different segments of the ligament are marked with dotted lines. The insertion segment displaying the greatest relative growth is denoted by  $s$ . The growth of the rest of the ligament is interstitial, which accounts for the displacement of the metal markers in the ligament downwards in relation to the epiphyseal plate. New tissue formed is indicated by light areas.

fluorescing bone could be observed between it and the connective tissue of the insertion.

3) *Implantation of metal markers:* When a metal wire loop was fixed in the bone between the site of insertion of the medial collateral ligament and the proximal epiphyseal plate of the tibia, the ligament insertion remained at its original site (Fig. 4) and the ligament grew in length corresponding to the length of the new part of the diaphysis formed between the marker and the epiphysis. The histological sections of the medial collateral ligament of the knee (Figs. 5 A and B) showed that the ligament lay on the surface of the periosteum to which it was partially attached. The diameter of the lengthened ligament was uniform from the level of the epiphysis to the metal marker and the ligament was attached to the diaphysis just distal to the marker. In six of 51 rabbits, the tendon or the ligament was inserted partially and in three entirely on the epiphyseal side of the metal marker in

5 A

5 B

Fig. 5 A (histological sections) Section from the proximal end of the tibia, the abnormally long medial collateral ligament runs along the right edge of the section. The location of a metal wire which had arrested displacement of the site of insertion is indicated by the arrow.

Fig. 5 B Normal insertion of the ligament on the left edge of the control sections.

the bone. In all cases the insertion was more distal from the epiphysis than in the controls.

«Insertion segment» (s in Fig. 4), refers to the distance between the metal markers in the bone and in the tendon (or ligament). The increase in the length of the insertion segment was  $75.2 \pm 2.9$  per cent of the increase in the metaphyseal length during growth.

In the control group, the displacement of the insertion site referable to the central part of the diaphysis was compared to the increase in the metaphyseal length during growth. The mean result was  $74.8 \pm 0.5$  per cent. The rate of displacement of the insertion site and the rate of growth of the «insertion segment» were thus 74.8 and 75.2 per cent

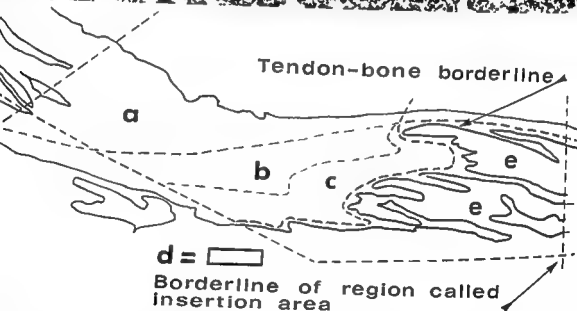

Fig. 6: Histological section (top) of the area of insertion of the pectineus muscle in the femur. The tendinous fibres run from the upper left corner of the microphotograph down to the right. There is bone on the right and bone marrow in the lower part of the picture.

The contour drawing shows how the region of the insertion area in the upper photograph was divided into five areas. The tendon-bone boundary is drawn with continuous lines. The broken line between areas a and b is a continuation to the boundary between the fibrotic and osteogenic layers of the periosteum. Area d (shaded in the picture) skirts the bony trabeculae. The zone between areas a and d has been divided by halving the distance of the above boundary lines at each point. Bone is denoted by e. The limits of the insertion area are drawn in straight broken lines. The line down to the middle (on the left) is parallel to the tendinous fibres, but the other limits are somewhat arbitrary.

Fig. 7: Graphic representation of the time course of the labelling index in the different areas, a, b, c, d and e, of the tendon insertion area (cf. Fig 6) The curves are based on results calculated from 64 autoradiographs. Each point represents the mean  $\pm$  SD of different specimens from one rabbit.

of the rate of growth of the metaphysis. These percentages were not statistically different.

4) *Incorporation of  $^3\text{H}$ -thymidine*: The longitudinal section of the insertion region of the pectineus muscle was divided into five areas (a, b, c, d, and e in Fig 6) and the labelling index (p) of each area was calculated. Fig 7 illustrates the labelling index of areas a, b, c, d and e as a function of time. The cells in the DNA synthesis phase were located chiefly in areas b and d judging from the preparation where the labelled cells had not yet divided (e.g. 23 hours after the injection). One day after the administration of the thymidine, labelled cells were numerous in area c, as well. After five days, the number of autoradiographically positive cells was decreased in areas b, c and d, but distinctly increased in area e, i.e. in bone.

The following is a summary of the changes seen in each area.

**Area a** Labelling index in the distal part of the tendon of the pectineus muscle, i.e. in area a, remained on the whole unchanged and there was no definite peak in the curve.

*Fig. 6: Histological section (top) of the area of insertion of the pectineus muscle in the femur. The tendinous fibres run from the upper left corner of the microphotograph down to the right. There is bone on the right and bone marrow in the lower part of the picture.*

The contour drawing shows how the region of the insertion area in the upper photograph was divided into five areas. The tendon-bone boundary is drawn with continuous lines. stronger radioactivity of the environment, could be seen on the tendon-bone boundary.

These results may be explained as follows: the rate at which tendinous tissue is produced in the insertion area is not the same in all parts of the area, but there is a zone in which the connective tissue is synthesized more rapidly than elsewhere in the environment. Part of the connective tissue formed at the time of administration of  $^{35}\text{S}$ -sulphate is incorporated in the bone and, following this, new connective tissue is laid down, especially in the zone of most rapid growth, which is not radioactive. Another possible explanation is that the radioactive connective tissue is in soluble form along the tendon-bone boundary and the pale zone is thus an artefact. However, the results using  $^3\text{H}$ -thymidine show that there are zones in the insertion region which have varying population kinetics, although the boundaries between them are not sharp. Relatively few mitoses take place in zone c compared with the adjoining zones. It is thus possible that on moving from area b to area c cellular proliferation diminishes and synthesis of the intracellular substance increases. Hence, the insertion area can be compared functionally with the epiphyseal plate in which it is possible to distinguish between, e.g., a cell proliferation layer and a layer of mature cells which synthesize the intercellular substance.

In addition, population kinetic studies established that the boundary between the tendon itself and the insertion area runs between zones a and b. The growth in area a was diffuse, as in the description of tendon growth given by Crawford (1950) and Hughes (1956). Also, the lengthening of the distance between the metal markers in the medial collateral ligament corresponds with this diffuse mode of growth of tendons. The results of the metal marker experiments shown in Fig 4 are in good agreement with the results obtained by other methods. Longitudinal tendon growth in the insertion is proportional to the bone growth originating from the epiphysis, and the most rapid tendon growth obviously occurs in zone c (Fig 6) close to the tendon-bone boundary. During normal growth the insertion area of the tendon shifts in regard to the central part of the diaphysis together with the formation of tendon, new bone originating along the tendon-bone boundary. Substances of the tendon tissue were retained in the bone during the growth process.

Area b. There appeared to be a peak at about five hours in area b.

Area c. Precise determination of the peak in the labelling index of the cells in area c was difficult, but the peak fell mainly within the region of half a day and certainly at a later time than in area b.

Area d. This area, the insertion region adjacent to the bone trabeculae, had a peak at one day.

Area e. In area e, i.e., within bone, no distinct peak was noted; the slope of the time course curve was initially ascending, but descended slowly thereafter.

## DISCUSSION

The autoradiographs obtained after labelling with  $^{35}\text{S}$ -sulphate showed that the radioactivity originally taken up by the connective tissue cells of the insertion area is deposited in the bone and appears farther from the site of insertion as the bone grows. Therefore, the tendon-bone boundary of the region of insertion moves further from the central part of the diaphysis because of the interposition of newly-formed, unlabelled bone. It should be noted that 95 per cent of the  $^{35}\text{S}$ -sulphate injected is excreted within five days in the urine and stools, and no appreciable radiosulphate is present in the blood 1–2 days after an intraperitoneal injection (Dziewiatkowski 1949). It has been demonstrated chromatographically that in slices of cartilage about 90 per cent of the total radioactivity is in chondroitin sulphate (Dziewiatkowski 1962). It is important to note, however, that the results obtained in the present study only reflect the behaviour of  $^{35}\text{S}$ -containing substances which are not removed from the tissue by the preparative techniques used.

The pictures obtained using the tetracycline technique confirm the findings of new bone formation along the tendon-bone boundary. New tendinous tissue must also form to replace that which has been incorporated in bone.

The metal marker experiments indicated that the zone of most rapid tendon growth is in the insertion area, close to the tendon-bone boundary. However, it is not possible to determine the zone exactly with this technique. Fig. 2 shows that two days after the administration of the  $^{35}\text{S}$ -sulphate the bone at the insertion area displayed a very narrow radioactive zone which remained in the bone. When 8–13 days had elapsed from the administration of the isotope, a relatively narrow, more weakly radioactive zone, clearly distinguished from the

stronger radioactivity of the environment, could be seen on the tendon-bone boundary.

These results may be explained as follows: the rate at which tendinous tissue is produced in the insertion area is not the same in all parts of the area, but there is a zone in which the connective tissue is synthesized more rapidly than elsewhere in the environment. Part of the connective tissue formed at the time of administration of  $^{35}\text{S}$ -sulphate is incorporated in the bone and, following this, new connective tissue is laid down, especially in the zone of most rapid growth, which is not radioactive. Another possible explanation is that the radioactive connective tissue is in soluble form along the tendon-bone boundary and the pale zone is thus an artefact. However, the results using  $^3\text{H}$ -thymidine show that there are zones in the insertion region which have varying population kinetics, although the boundaries between them are not sharp. Relatively few mitoses take place in zone c compared with the adjoining zones. It is thus possible that on moving from area b to area c cellular proliferation diminishes and synthesis of the intracellular substance increases. Hence, the insertion area can be compared functionally with the epiphyseal plate in which it is possible to distinguish between, e.g., a cell proliferation layer and a layer of mature cells which synthesize the intercellular substance.

In addition, population kinetic studies established that the boundary between the tendon itself and the insertion area runs between zones a and b. The growth in area a was diffuse, as in the description of tendon growth given by Crawford (1950) and Hughes (1956). Also, the lengthening of the distance between the metal markers in the medial collateral ligament corresponds with this diffuse mode of growth of tendons. The results of the metal marker experiments shown in Fig. 4 are in good agreement with the results obtained by other methods. Longitudinal tendon growth in the insertion is proportional to the bone growth originating from the epiphysis, and the most rapid tendon growth obviously occurs in zone c (Fig. 6) close to the tendon-bone boundary. During normal growth the insertion area of the tendon shifts in regard to the central part of the diaphysis together with the formation of tendon, new bone originating along the tendon-bone boundary. Substances of the tendon tissue were retained in the bone during the growth process.

## SUMMARY

The aim of the present study was to elucidate the displacement of the sites of insertion of tendons and ligaments in regard to the central part of diaphysis during growth of tubular bones. The problem was studied using  $^{35}\text{S}$ -sulphate and autoradiographic technique; tetracycline technique and metal markers fixed to tendons, ligaments and bone;  $^3\text{H}$ -thymidine and stripping film autoradiographic technique. A total of 144 growing rabbits and additional control animals were used for the experiments.

Two different processes were noted as occurring simultaneously in the region of insertion during growth: longitudinal growth of tendon or ligament in the insertion area which is proportional to epiphyseal growth; and direct incorporation of newly-formed tendinous tissue in osseous tissue.

According to these events, the sites of insertion of tendons and ligaments in long tubular bones remain relatively unchanged topographically despite bone growth.
